Nomenclature

I_{fd} = field current of generator or exciter armature current

E_{fd} = field voltage of generator or armature voltage of exciter

ψ_{fd} = generator field flux linkages

e_d' = voltage proportional to generator field flux linkages

i_d = generator load current in direct axis

i_q = generator load current in quadrature axis

e_{d1} = direct axis component of generator terminal voltage

e_{q1} = quadrature axis component of generator terminal voltage

e_t = terminal voltage of main generator

x_d = generator direct axis synchronous reactance

x_q = generator quadrature axis synchronous reactance

x_d' = generator direct axis transient reactance

x_e = system reactance

δ = generator load angle between excitation axis and infinite bus voltage

θ = generator load power factor

T_e = electrical torque of main generator

T_m = mechanical torque input to generator rotor

e_d = infinite bus voltage in direct axis

e_q = infinite bus voltage in quadrature axis

T_2 = effective exciter time constant

T_{do}' = generator open circuit time constant

H = inertia constant = $\dfrac{0.231WR^2(\text{rpm})^2 \times 10^{-6}}{\text{kilovolt-amperes (base)}}$ kilowatt seconds / kilovolt-amperes

e_m = voltage applied to terminals of induction motor of exciter set

P_m = power output of induction motor of exciter set $= \left(\dfrac{V}{V_e}\right)^2 P_e$

s = slip of motor-driven exciter set

k_T = exciter armature voltage saturation constant in equation 8A

k_r = constant representing regulator action in equation 8B

Critical switching time—maximum allowable time to clear fault and retain generator stability

Buck-boost amplidyne regulator—rotating amplifier in exciter field circuit, bucking or boosting the field voltage, with a static regulator

Synopsis: Rectifier tubes have demonstrated their reliability over many years of service in industrial applications and to a limited extent on excitation systems. Thus in an effort to obtain more reliable and continuous excitation service, the decision was made to apply an electronic ignitron rectifier exciter to each of two new 37,500-kva 3,600-rpm turbogenerators in the Warren Plant of the Pennsylvania Electric Company. The power source to the exciter is a small 6-phase generator connected to the same shaft as the main generator, and is therefore free from system electrical disturbances. The first exciter was tested with a large synchronous machine in the shop which demonstrated that it was fundamentally sound in its operation. Additional tests were made after installation in the power plant and, after certain changes, both exciters have given excellent service. One has been in service for about six months, and the other for over a year. There is no other source of excitation for these two generators.

IN recent years it has been proved that synchronous generators can be operated over long periods of time without shutdown. In fact, the reliability of turbogenerators is such that more and more emphasis and effort is being placed on getting excitation system which approaches the reliability of the a-c generator. The electronic exciter may prove to be one answer to the demand for improved excitation. This paper describes the design, shop testing, and field testing of an electronic exciter for a 37,500 kva turbogenerator.

Requirements

To provide continuous service from a generator and fulfill other practical considerations, the electronic exciter should meet the following requirements:

1. It must be rugged, reliable, and capable of supplying continuous excitation over long periods of time. Ideally, it should never be the cause of a generator shutdown.

2. To give continuous service, component parts which require maintenance or replacement must be easily accessible and arranged so that a portion can be removed from service without affecting the generator load.

3. It should have a minimum of moving parts.

4. It must be capable of supplying the required excitation during system disturbances and have sufficient response to maintain stability.

5. It must be capable of operating over a broad range of d-c field current, from generator no load or less to maximum output. Short time values of field current much greater than full load requirements also must be available.

6. The supply to the exciter must be a reliable source free from system disturbances.

7. It must have anode circuit breakers with automatic reclosing to clear and restore to service an ignitron tube which may have an arc back. In case of tube failure the anode circuit breaker must lock out in the open position.

Description of Apparatus

Basic Design

The original scheme as designed is shown in Figure 1. A 6-phase generator connected directly to the shaft of the main 3-phase generator, supplied 60-cycle voltage to a 6-phase star ignitron tube rectifier, which supplied d-c power to the 250-volt field of the main generator. The field voltage of the main generator was regulated by an electronic regulator which controlled the firing point of the ignitron tubes and was set to maintain the 11.5-kv output voltage constant.

The 125-volt field of the 6-phase alternator also was supplied from the 6-phase rectifier. A motor-driven rheostat reduced the 250-volt output of the rectifier to the required 125 volts and also varied the field voltage to maintain a constant output voltage on the 6-phase generator, the action of the rheostat being controlled by a beam-type regulator. The unit is started up by energizing the field of the 6-phase generator from the station battery until the ignitron rectifier puts out the required voltage. After this the excitation for the 125-volt field is transferred from battery to rectifier and the unit continues self excited.

In service, it was found that the operation of the main generator required that the electronic regulator vary the output voltage of the ignitron rectifier frequently to maintain constant output voltage on the main generator. This also varied the voltage impressed on the field of the 6-phase alternator and required the motor-driven rheostat to operate just as frequently to keep the output voltage of this generator constant.

Since such frequent operation of a motor-driven rheostat is undesirable, the design was modified to that shown in Figure 2. This design is similar to that in Figure 1 except that the field of the 6-phase alternator is supplied by a 6-phase delta star thyratron rectifier, the primary of whose transformer is connected to three phases of the output of the 6-phase alternator. The thyratron tubes are fired at zero delay and the field voltage of the 6-phase alternator is varied by the same motor-driven rheostat. In this design, the output voltage of the

Figure 3 (right). Proposed design of electronic excitation system for future installation

thyratron rectifier is practically independent of the output of the ignitron rectifier. The motor-driven rheostat operates only when there are sudden large changes in the field current of the main generator, which are infrequent.

The ignitron tubes are divided into three groups of two tubes each, the two tubes of each group being connected to diametric phases of the 6-phase alternator through a 2-pole high-speed anode circuit breaker. Thus if a circuit breaker is opened, both tubes are de-energized. Each anode circuit breaker is provided with a field discharge switch in series with the field discharge resistor of the main generator so that if all three anode circuit breakers are opened, a discharge path is provided for the field of the main generator.

Each group of two tubes, its anode circuit breaker, grounding switch, firing tubes, and associated control circuit, are located in one of three individual compartments of the main rectifier cubicle. By opening the anode circuit breaker grounding switch, and firing tube circuit breaker, either of the ignitrons or associated firing tube can be replaced without disturbing the other four ignitron tubes which will continue to operate.

The six thyratron tubes supplying the field of the 6-phase generator are each provided with a disconnecting circuit breaker so that any one of these tubes may be replaced while the other five are in operation.

In Figure 3 is shown a scheme used in the Seward Plant of the Pennsylvania Electric Company. In this scheme, the 6-phase ignitron rectifier is supplied through a transformer by a standard 3-phase generator direct connected to the shaft of the main generator. The field excitation for this rectifier generator is in turn provided by a 3-phase bridge selenium rectifier supplied from a 3-phase permanent magnet generator which is direct connected to the shaft of the rectifier generator. No attempt is made to control the output voltage of the rectifier generator.

Ignitron Tube Firing Circuit

The firing circuit for each ignitron tube is of the anode firing type. A thyratron tube is connected in parallel with the ignitron through its ignitor. The thyratron is made conductive when its anode voltage is positive with respect to its cathode and its grid is released. It passes a current through the ignitor which initiates a cathode spot in the ignitron and fires it. When the ignitron fires, its low arc drop puts out the thyratron. The firing circuit is shown in Figure 4. Should the ignitron fail to conduct, the thyratron will try to carry the load current but will be tripped out by the circuit breaker in its anode circuit.

Ignitron Rectifier Direct Voltage Control

The output of the ignitron rectifier is varied by controlling the point at which the ignitron tube is released on its anode voltage wave. This point in turn is determined by releasing the control grid of the firing tube. The release of the thyratron tube is controlled by a sine wave grid transformer, a rectox supplying a fixed positive bias, a rectox supplying variable negative bias for manual control, and an electronic regulator supplying a variable negative bias for automatic control. The circuit is shown in Figure 4.

The sine wave voltage impressed upon the grids of the firing tubes is delayed almost 90 degrees from the tube anode voltage and is connected in series with the positive and negative biases. Varying the negative bias determines the point at which the grid voltage becomes more positive than the characteristic grid voltage of the firing tube and releases the tube for conduction. The use of both a positive and negative grid bias provides for a wide angle of control.

Electronic Voltage Regulator

The main generator voltage regulator employed with the electronic exciter is an

Figure 2. Present design of electronic excitation system as in operation

electronic circuit shown in Figure 5, consisting of two d-c amplifiers. The first d-c amplifier is a high gain voltage amplifier using a *5693* tube, the output of which is worked into a power amplifier, using a *6V6GT* tube. The high gain voltage stage gives the regulator its high degree of sensitivity and the power amplifier supplies the necessary variable negative bias voltage for controlling the thyratron firing tubes which, in turn, control the ignitron tubes.

A modified Wein bridge is used in the input circuit as a filter for the 360-cycle ripple obtained from the output of the 3-phase full-wave dry-type rectifier, connected through a potential transformer to the main generator. The bridge-type filter was used in order to avoid adding any undue time constants to the regulator circuit.

Ignitron Tube Auxiliary Anode

Auxiliary anodes are provided in the ignitron tubes to provide more positive pickup. The auxiliary anode is located close to the mercury pool and strikes an arc as soon as the ignitor is fired. The arc then transfers to the main anode as soon as it becomes sufficiently positive to pick up the arc. The auxiliary anode voltage usually is 30 degrees leading with respect to the main anode. The circuit is shown in Figure 4.

Ignitron Tube Cooler System

An arc drop of approximately 16 volts in the ignitron tubes, generates heat within these tubes, the magnitude of which varies with the load. This heat must be dissipated or the tubes will become inoperative. To carry away this heat, a recirculating water system is provided which circulates water through the ignitron tube water jackets, this water in turn being cooled by a water to water heat exchanger. A schematic of the cooling system is shown in Figure 6. The heat exchanger shell, water pump, and associated apparatus are located in a cabinet adjacent to the rectifier cabinet.

The water pump takes the heated water from the ignitron tubes, forces it through the heat exchanger shell where it is cooled and back again through the tubes. Raw water from an outside source passes through the heat exchanger and acts as the coolant. The temperature of the water passing through the ignitron tubes is controlled by a temperature regulating valve which regulates the quantity of raw water passing through the heat exchanger, and whose control bulb is located at the outlet to the ignitron tubes. A pressure regulator keeps a constant raw water pressure on the system. An expansion tank provides a reservoir of recirculating water and also maintains a positive pressure at the intake to the water pump to prevent air from entering the system.

Protection and Alarm Circuits

A number of devices are provided to warn of failures and impending troubles.

Arcbacks

In case of an arcback, the tube which arced-back and its companion tube are disconnected from the 6-phase generator by the anode circuit breaker which recloses immediately once the arcback is cleared. If the tube arcs-back again within a preset time, the circuit breaker will open again and lock out after which it should be checked before it is reclosed manually.

Arcback counters are provided on each tube which count the cumulative number of arcbacks. A periodic check of these counters will indicate if any tube has had an excessive number of arcbacks and the tube can be removed before an actual failure results.

Anode heaters are provided on each tube to keep the anode warm during light load periods and shutdowns to prevent mercury from condensing on the anode surface. Such condensation may cause arcbacks.

Misfires

In case the firing tube fails to fire the ignitor, a misfire light will indicate. The misfire lights are neon bulbs connected through a transformer across a resistor in series with the auxiliary anode as shown in Figure 4. When the auxiliary anode picks up, voltage appears across the resistor and lights the neon bulb. If the auxiliary anode does not pick up due to failure of the ignitor to fire, the bulb remains dark. If an ignitron tube should fail to conduct, the firing tube in parallel with it will try to carry all of the load current and the circuit breaker in its anode lead will trip it out giving an indication at the control desk.

Tube Over Temperature

If one of the ignitron tubes becomes overheated, an over temperature switch will operate and give warning. The tube can then be removed as stated previously and checked.

Figure 4. Firing control circuits for the ignitron tubes

Figure 5. Schematic diagram of the electronic regulator for generator voltage

Failure of the Water Pump

If for some reason the water pump breaks down or fails to deliver the required pressure, a pressure relay operates and can be used to warn the operator and operate a motor-driven valve which will supply emergency water to the ignitron tubes. This emergency water is made to flow through the heat exchanger by a check valve in the exhaust of the water pump, through the ignitron tubes, the expansion tank, and out the overflow. The water pump can then be isolated by valves and serviced.

A bypass is provided around the pressure and temperature regulators in the raw water system so that they can be removed and serviced without interruption, the raw water being regulated manually.

Failure of Thyratron Rectifier Tubes

Failure of any of the thyratron rectifier tubes can be noted by visual inspection and the tube isolated by its respective circuit breaker and replaced.

Field Failure

A sudden failure of main generator field current operates a current relay in the field leads and causes an emergency shutdown of the generator unit.

Voltage Regulator Potential Failure

A sudden failure of the potential to the electronic voltage regulator will cause the operation of an under-voltage relay. The operation of this relay transfers the exciter control from the electronic voltage regulator to manual control and a preset value of excitation.

Exciter Characteristics

Current Output

Each of the six ignitron tubes in the exciter has a continuous current rating of 200 amperes. Thus with six tubes, which are normally in service, the exciter can supply a continuous direct current of 1,200 amperes as against the required full load excitation on the main generator of about 600 amperes. With four tubes a continuous current of 800 amperes can be supplied which also is in excess of the generator full load requirement. Since each tube has an overload capacity of 300 amperes for two hours, even two tubes can supply practically full load excitation for a short time.

The normal voltage across the main generator field is about 220 volts. The ceiling voltage at no load on the exciter with six tubes is about 375 volts, and with four tubes about 355 volts. With two tubes the ceiling voltage at no load on the exciter is about 265 volts.

The field winding of the main generator has a resistance of about 0.356 ohm at 75 degrees centigrade. Thus with a normal voltage of 214 volts, the required 600 amperes will flow. At maximum voltage, with six tubes in service, the voltage across the field increases to about 330 volts and the field current increases to about 920 amperes. With four tubes the maximum voltage across the field increases to about 310 volts, and therefore the field current increases to about 870 amperes.

Response

With the electronic regulator, whenever the voltage on the terminals of the main generator changes from the desired value, the voltage output of the exciter tends to go to maximum or minimum voltage. For a drop in voltage the angle of delay in the firing of the ignitron tubes is reduced to zero until the terminal voltage is back to normal. For a rise in voltage the angle of delay is a maximum. The exciter has a rate of response in excess of minimum speed of response ratio of 0.5 used on most power system excitation systems.

Recovery After Tube Arcback

As demonstrated by tests, a tube arcback has a relatively minor effect on the terminal voltage of the main generator. The voltage is affected for only a few cycles and the maximum deviation from normal is less than 5 per cent. Thus by the high-speed operation of the anode circuit breaker, the tube is removed from service long enough for elimination of the arcback and then reinserted into service.

Sensitivity to Normal System Voltage Regulation

In conjunction with the electronic regulator, the electronic exciter is very sensitive to changes in generator-terminal voltage and corrections are made very rapidly. Even small changes from normal voltage instantly affect the output of the exciter and therefore high speed of

response is obtained for minor variations in voltage.

Effects of System Frequency

The electronic regulator and the electronic exciter are not affected by variations in system frequency over a wide range. Even if the system frequency should drop to as low as 50 cycles, the exciter system will maintain substantially the same generator terminal voltage as normally exists for 60 cycles.

Laboratory Tests

The electronic exciter was tested before it was shipped. The 625-kva 6-phase 3,600-rpm generator was driven by a d-c motor at rated speed. The output of the rectifier was fed to the field of a 20,000-kva High Power Laboratory Test machine. The normal no-load field current of this test generator was about 600 amperes which is full-load field current on the generator for which the exciter was built.

A large number of tests were made to demonstrate the versatility of the exciter. Many oscillograms were recorded and data taken from typical tests are shown herein. These tests were made with the field of the 6-phase generator being supplied through a rheostatic regulator from the output of the main exciter as shown in Figure 1. Thus the record of the current and voltage of the 6-phase generator field are not as uniform as they would be for similar tests on the actual field installation which is as shown in Figure 2. The actual test results also have more variations in the main generator field current and voltage than would be the case for the final layout.

Typical results showing the variations in main field current (I_f), main field voltage (E_f), 6-phase generator field current ($I_{f6\phi}$), 6-phase generator field voltage ($E_{f6\phi}$) and the terminal voltage of the 20,000-kva test generator (E_g), plotted against time in cycles, are given in Table I.

In each of the tests when 40,000 reactive kilovolt-amperes of load was applied to the test machine the field current increased suddenly to about 1,800 amperes, induced from the machine armature. In every test the exciter operated properly. Tubes were switched out and in for all combinations and in each test the voltage was stabilized quickly.

Figure 12 is an oscillogram showing the various currents and voltages for one test where the excitation to the 6-phase generator was transferred from the battery source to the main rectifier. It will be noted that the field voltage is not what is regarded commonly as d-c voltage, but rather a whole series of half waves having an average value which is a d-c voltage. The field current, however, is very nearly a smooth direct current record.

When starting, the excitation for the 6-phase generator field was obtained from a separate d-c service. After voltage was built up on the output of the exciter, the

In about 35 cycles the voltage was normal

6-phase generator field was transferred automatically to the output of the exciter. This is the normal start-up procedure for the actual installation where the separate d-c source is the 125-volt station battery.

Field Tests

With the installation of the first of the two electronic exciters as described previously, field tests were planned to determine the best operating procedures and the extent of the capabilities of this form of excitation. The tests which were performed are discussed in the following. Figure 13 shows an electron exciter installation.

Stability Test Under Full Automatic Control

The first stability test was made on the original design of the exciter as shown in Figure 1 where excitation to the main generator and the 6-phase generator was obtained from one 6-phase ignitron rectifier. As stated previously, a voltage regulator controlled the output voltage of the 6-phase generator by means of a motor-operated rheostat in the field circuit.

When excitation to the main generator was varied by means of the electronic voltage regulator, the field voltage of the 6-phase generator also changed. This necessitated operation of the 6-phase generator voltage regulator and the motor-operated rheostat to attempt to maintain its terminal voltage, but it caused an excessive number of operations of the 6-phase generator voltage regulator and motor-operated rheostat.

The system was modified to use a small 6-phase thyratron rectifier operating from three phases of the 6-phase generator as a source of d-c excitation to the 6-phase generator. This eliminated the excessive number of operations of the 6-phase generator regulator and the apparent instability between the two voltage regulators. After the separation of the two regulator circuits, operation was satisfactory under fully automatic control. No antihunt devices were found necessary under no-load conditions on the main generator.

With the above changes in the excitation system, the exciter operated satisfactorily under adverse conditions with various numbers of tubes made inoperative, with the main generator carrying load.

Automatic Control Test

The first tests were performed on the main ignitron rectifier exciter with the generator under the control of the electronic voltage regulator, but with the generator disconnected from the system. The anode circuit breaker for one pair of ignitron tubes was opened and no effect was noted on the generator voltage. A second anode circuit breaker was opened, leaving only a single pair of ignitron tubes

Figure 12. Oscillogram showing currents and voltages when excitation to 6-phase generator was transferred from battery source to the main rectifier

Figure 13. Electronic exciter in place showing the two switchgear compartments on the left, the heat exchanger compartment on the right, and the three tube compartments

in operation, and again no effect was noted on the generator voltage. During these tests of eliminating various pairs of ignitron tubes, a cathode-ray oscilloscope was connected across each of the three phases of the main generator by means of potential transformers to view the wave shape of the voltage and no harmonics or wave distortion was noted on the screen.

The same tests were again performed as described previously with the main generator operating in parallel with the rest of the system and carrying consecutive loads of 10,000-, 20,000-, and 30,000-kw at approximately 90 to 95 per cent lagging power factor. These tests showed no appreciable effects on over-all operation of the excitation system and no noticeable change of the reactive kilovolt-amperes from the generator or the generator terminal voltage.

Manual Control Tests

Similar tests to those just describe were made with the electronic exciter under manual control. Under no-load and lightly-loaded conditions of approximately 10,000 to 15,000 kva, a slight rise of about 3 per cent of the main a-c generator voltage was noted when one anode circuit breaker was opened, removing a pair of ignitron tubes from the circuit. This was probably caused by changes in the distortion of the voltage wave form in the control circuits.

With the opening of the second anode circuit breaker, a decided drop of about 7 per cent of the main a-c generator voltage resulted.

Six-Phase Auxiliary Rectifier Tests

With the main generator carrying 40,000 kw, the maximum excitation voltage required for the 6-phase generator to maintain its output voltage constant is 95 volts. The removal of two electrically adjacent thyratron tubes, an extreme condition, gives 97 volts of direct current. The difference between these two voltages is taken up in the drop across the rheostat in the field circuit.

Operating Technique

Normal Start-Up

The normal starting procedure can be covered in three to four steps, depending on the particular method which the operator prefers to synchronize the generator to the line after it has been brought up to speed.

With the generator at synchronous speed, the operator checks the controls, making sure that the anode circuit breakers are open, and that the 6-phase generator voltage regulator is set for automatic operation. The exciter is then ready to be energized. The field flashing circuit breaker is closed which puts battery voltage on the 6-phase generator field. This circuit breaker is held closed manually until the 6-phase generator field voltmeter and ammeter have indicated and come to rest. The control switch to the field flashing circuit breaker is then released, which transfers the excitation to the thyratron rectifier. When the 6-phase generator has stabilized itself, the anode circuit breakers are then closed. The voltage of the main generator is brought up to the desired value by manual adjustment. The machine now may be synchronized to the line under manual control or the electronic voltage regulator may be placed in service before synchronizing.

Normal Shutdown

For normal shutdown, the operator performs the usual operation of removing the generator from the line, then opens the three anode circuit breakers, thereby removing all excitation from the main generator. In order to remove voltage from the 6-phase generator, the voltage regulator is taken out of service and the motor-operated rheostat is run to the all-in position which causes the voltage to collapse.

Application

System Disturbances

This type of electronic exciter is a self-contained unit having its own source of power from the 6-phase generator which is entirely free from system disturbances. In this respect this electronic exciter is comparable to other exciter systems where direct-connected commutator exciters are used. It is better in this respect than a separate motor-generator set where the power source to the motor is subject to system disturbance. If an auxiliary generator is used on the same shaft with the main generator and this auxiliary generator supplies a motor-generator exciter, then the exciter is free from the effects of usual system disturbances.

Reliability and Maintenance

The electronic exciter, in effect is more than one exciter in one set of equipment because the most vulnerable parts, namely the tubes, can be removed from service, two at a time, without interfering with normal excitation to the generator. In the event of a tube failure it, along

with a companion tube, is removed automatically from service by an anode circuit breaker and can be replaced and restored to service. For other types of excitation systems, certain types of failures will cause an immediate generator outage. It is expected that this type of electronic exciter system will be relatively free from troubles which will cause generator outages; however, experience must supply the proof.

Required Space

The electronic exciter requires more space and volume than conventional-type direct-connected commutator exciters. However, it does not require more and probably not as much space and volume as a motor-generator type separate exciter. The electronic exciter does not necessarily require critical floor space because the exciter under discussion is mounted on a balcony adjacent to and on the same level with the generator terminal leads under the generator.

Voltage Regulation and System Faults

The output of the electronic exciter can be varied over a wide range by controlling the point on the voltage wave at which tube firing takes place. No generator rheostat is required to get the full operating range of field currents for the generator. Since the voltage regulator controls only the firing circuit, it can be and is a low energy device; in this case it is an electronic regulator. The electronic exciter also has the capacity to build up to its ceiling voltage practically instantaneously, making it well suited for high speed of response when increased excitation is required for system transient stability.

Due to the time constant of the generator field circuit, the time required for the regulator and exciter to take action is of little significance since all types of regulators take action in about three cycles or less. The speed with which ceiling voltage is reached, and the magnitude of the ceiling voltage, however, affect the speed at which generator field current is increased. The electronic exciter has high speed action, a fast change to ceiling voltage, and a high ceiling voltage.

Due also to the time constant of the generator and to high-speed relays and circuit breakers, the electronic exciter will not cause higher short-circuit currents on system faults. For faults which hang on for longer periods of time the currents may be affected slightly, but the reactance of the generator increases with time, thus introducing a limiting effect.

Cost

The electronic exciter costs between two and three times the cost of a conventional direct-connected exciter. The cost of a spare excitation source, however, should be considered when comparing the over-all cost of excitation facilities. No spare source of excitation is required with this type of electronic exciter. The over-all cost must therefore be evaluated for each application.

Advantages

1. Parts may be maintained or replaced with rest of unit in service.
2. It is a static device.
3. Has inherent qualities of a conventional direct-connected exciter with respect to freedom from system disturbances, high-speed excitation, range of excitation, and so forth.
4. Expected to prevent generator outages caused by failure of excitation.
5. Equivalent to more than one conventional exciter.

Disadvantages

1. High cost as compared with conventional types of exciters having d-c generators direct-connected or motor-driven may be, in some cases, a detrimental factor.
2. Requires more space and volume than a conventional direct-connected exciter although the space and volume taken by conventional spare exciters must be evaluated.
3. Has many more component parts, consisting of control transformers, tubes, control wiring, contacts, and so forth than are required by conventional excitation systems.

Conclusions

1. Laboratory and field tests under normal and abnormal conditions, indicated that the electronic exciter would perform in a manner which would provide dependable excitation.
2. The service record, of over one year, indicates that the electronic exciter is providing satisfactory excitation for normal operation and under system fault conditions.
3. The separate a-c generator provides a source of power for the exciter which is free from system disturbances. It is therefore a type of direct-connected exciter.
4. This exciter has a high speed of response and a high ceiling voltage.
5. This exciter is equivalent to more than one exciter since it is possible to provide continuous excitation while parts of the exciter are out of service for maintenance.
6. The cost of this excitation system is in excess of that for a conventional direct-connected exciter.

Discussion

H. A. P. Langstaff (West Penn Power Company, Pittsburgh, Pa.): The authors have given us a very interesting and rather complete story involving the use of the electronic exciter which should prove of considerable value to the industry. I note that the Pennsylvania Electric Company is not providing a spare exciter; therefore, it must be assumed that the operators must change tubes with the exciter remaining in service. This the West Penn Power Company has not done even though facilities are provided. We have found that when the exciter is taken out of service to make a tube change, we experience an epidemic of bad tubes and we end up by changing more than one before the exciter is returned to service. Most failures have been due to loss of vacuum, and we suspect there is some connection between a tube that has been in service for a while and allowed to cool, causing loss of vacuum.

If the manufacturers could overcome this vacuum-tube problem, it would prove the electronic exciter much more economical with each tube costing about $300.00, this becomes expensive.

The exciters discussed in this paper have several improvements over the West Penn unit which, of course, is to be expected. The duplication of the water cooling system would reduce the outages which are caused mostly by the pump.

The life of the Thyratron tubes with the West Penn unit has been somewhat better than $1^1/_2$ years, and this will be improved by changing to the new design, namely, type *WL-105*, replacing the old type *K U-676*, each costing approximately $30.00.

The following paragraphs pertain to electronic exciter performance at the West Penn Power Company.

In 1944 when the West Penn Power Company was planning for the 80,000-kw generator addition to its Springdale Power Station, extensive consideration was given to the type of excitation system. At that time generator shaft-driven exciters were being recommended. In 1937 the company installed a 50,000-kw, 3,600-rpm topping unit in Springdale and this included a generator shaft-driven exciter with a standard shunt-wound pilot exciter. This company's experience with this unit resulted in our being reluctant to provide a shaft-driven unit for the new Number 7 generator.

The first five units for this station varied in capacity from 25,000 to 50,000 kw over a period of six years, namely, 1920 to 1926—all excited from motor-driven or motor- and steam-driven overcapacity exciters supplemented by spare units. Excitation troubles were quite limited, and the difficulties with the direct-connected exciter on the Number 6 topping unit prompted considerable reluctance in repeating such an installation for

the proposed largest unit on the system. Various combinations were considered, resulting in the selection of the electronic exciter having a rating of 860 amperes at 250 volts. It was understood this would be an experimental installation; nevertheless, the background of experience with ignitron rectifiers and various types of application substantiated the decision. It was understood the unit would be designed and delivered about a year in advance of the generator. This period should have provided ample time to eliminate the possible growing pains. This schedule was not met, and the company finally decided to use the dual-driven 300-kw 250-volt exciter then being used for our Number 5 50,000-kw generator installed in 1926. This 23-year old combination is still in use, and there has been no excitation or electrical failure of any kind causing an outage to this 80,000-kw generator which went in service in December 1945.

The electronic exciter went through a series of factory tests and finally was delivered without the compensating transformers which were to have been installed in the generator leads. During installation it was decided to connect the rectifier transformer to the Number 5 section of the existing station auxiliary bus and to date it remains so connected. The new station auxiliary switching for the Number 7 unit included a control cubicle with circuit breaker, and so forth, for the electronic exciter transformer but it has never been used as such.

It also was decided that the electronic exciter would first be used with the smallest station unit, namely, 25,000 kw. The operating group was quite reluctant to take any chance on loss of station capacity in view of system load conditions.

The electronic exciter went in service on March 12, 1946, providing excitation for the 25,000-kw unit during off-peak periods. The exciter was out of service from March 27 until June 17 because of damage to the electrolytic arresters which provide surge protection to the generator field. This damage was caused by circulating current rectified by the lightning arrester at the rate of six impulses per cycle. On June 17 the exciter was returned to service and shortly thereafter the Number 1 generator-field-circuit resistance-to-ground was found lower than that of the other machines.

In order to inhibit some parts of the cooling system where iron was used, it was recommended that a 5 per cent solution of dichromate be added, and this accounts for the high conductivity. Considerable time was lost in eliminating this condition.

On August 13 the exciter was connected to the Number 2 station unit, a duplicate of Number 1, where it remained in service until January 3, 1947. During this period it was tested for operating, exciting both Number 1 and Number 2 generators simultaneously for a period of four hours. Considerable improvement was noted in the regulation of the 25-kv transmission voltage as compared with the Tirrell vibrating regulators.

On January 3, 1947, the electronic exciter was transferred to the Number 5 50,000-kw generator where it continues to provide dependable excitation.

During the three years that this exciter has been in use there have been a number of arc backs and misfires, but in no case have we ever lost a generator due to these or any other conditions. Numerous tests have been made to determine what might happen in case of loss of tubes and the like. On February 1, 1947, when supplying excitation for Number 5 generator, three ignitron tubes were removed from service, first with a load of 29,000 kw, then 40,000 kw, and finally with full load of 50,000 kw. The test was successful, and this materially improved the operator's confidence in the exciter. With two tubes out of service the main exciter voltage was 350 volts, with three tubes out it was 275 volts, and with four tubes out of service it was 200 volts. The generator required 210 volts across the field to supply the necessary excitation for 50,000 kw at 94 per cent power factor, with a terminal voltage of 11,750 volts. These tests prove that satisfactory excitation could be provided with three tubes out of service, but not quite satisfactory with four tubes out.

During the three years the exciter has been in service, several changes have been made. Fuses originally in the misfire circuits have been replaced with small deion circuit breakers, thus reducing the time a firing circuit is out of service following a misfire. Anode heaters have been added to prevent condensation of mercury vapor on anodes during periods that the equipment is out of service for maintenance, thus reducing the number of arc backs experienced immediately after placing the equipment back into service.

All arc backs have been properly cleared by the tripping of the proper anode circuit breakers and all tubes restored to service by their immediate reclosing. The outage period has proven of such short duration that no noticeable reactive swings were observed. Most arc backs have occurred while the exciter was under the control of the silverstat regulator. Even though the anode circuit breaker had not successfully closed, the regulators would have corrected the excitation, thus preventing violent swings in load and reactive kilovolt amperes.

The original power tubes supplied with the equipment have all been replaced. Three tubes lasted 26 months, one 25 months, and one had to be replaced within two months because it was defective. The life of the balance of the tubes has averaged somewhat better than one year. There has been a second replacement of three tubes. All of the first set of Thyratron tubes have been replaced, and of these there have been two second replacements.

Table I of the discussion gives the details of the ignitron tube record. Loss of vacuum has been the major cause of replacements. Any or all of these tubes can be replaced without removing the rectifier from service, but unfortunately the operators have not been so convinced; thus we have an unused facility.

The over-all efficiency of this exciter is approximately 82 per cent as determined by our own measurement of a-c input to the power supply transformer and the d-c voltage and current to the generator field. This includes power supply to the heat-exchanger unit.

This exciter was furnished by the manufacturer on an experimental basis with the understanding that if proven satisfactory, West Penn Power Company would have the right to accept or reject the unit. When the generator was installed, foundations were provided for the future installation of a direct-connected exciter. To date we have no intention of providing a direct-connected exciter. The application of the electronic exciter to the unit it was intended for is still in question. An additional expenditure for cable connections is required, and this has not as yet been justified. Existing operating conditions are quite satisfactory and may remain so as long as present load conditions continue. The 300-kw duel-driven exciter was equipped with a pilot exciter and this, along with a *BJ-90* regulator, continues to provide a very dependable excitation system. There are provided switching facilities whereby the Number 7 field may be excited from a spare exciter bus but this is very seldom, if ever, used. The West Penn Power Company, as well as the manufacturer, have gone to considerable expense in completing this experiment, and after considerable review of expenditures the West Penn Power Company and the manufacturer agreed upon a purchase price which, of course, was somewhat in excess of the omission price for the direct-connected exciter which was included in the contract for the generator.

When purchasing the two 80,000-kw units for the new Mitchell station, it was decided to accept the direct-connected exciter and Rototrol pilot arrangement. A spare motor-driven exciter and Rototrol pilot have been provided for use with either generator. Twelve years' experience with the direct-connected exciter on Number 6 topping unit at Springdale and one year's experience with the first unit at Mitchell have not proven direct-connected exciters to be as dependable as the old motor-generator sets or the electronic exciter at Springdale.

The possible economies of the direct-connected exciters must be recognized; nevertheless, the service and the expense incurred by failures and the loss in generation may more than account for these economies.

The two 20,000-kw package-type 3,600-rpm generators for the new Milesburg station now being constructed include direct-connected exciters with standard shunt-type pilot exciters. A spare motor-generator set with shunt-type pilot is being installed.

A. P. Colaiaco, A. A. Johnson, and J. E. Reilly: The ignition tube life experienced on

the electronic exciter at the Springdale Station of the West Penn Power Company as related by Mr. Langstaff is considerably shorter than that experienced with similar ignitron tube electronic exciters and on many other industrial installations.*

In F. M. Porter's and J. H. Kinghorn's discussion of Excitation Improvement,[1] they point out that on the three electronic exciters operated by their organization, the actual operating life of the ignitron tubes has averaged 32,680 hours or almost 4 years. Similar ignitron tube life has been experienced on several hundred other industrial applications.

In one installation in particular, the New Carlisle Station of the Indiana and Michigan Electric Company, a Westinghouse electronic exciter using ignitron tubes has operated for the past $7^1/_2$ years with the same set of six ignitron tubes. A life of $7^1/_2$ years for a group of six tubes is unusual. However, it does emphasize that short tube life such as experienced by the Springdale electronic exciter* is also unusual and must have an underlying cause which can be remedied.

An investigation should be made of the Springdale electronic exciter to determine the cause or causes of these excessive tube failures and steps should be taken to correct them.

*Note that tube 26317 listed in Table 1 of the discussion as having been removed from position 1 on 5-20-48 with 26 months' life was later installed in position 5 on 6-1-48 where it operated for seven more months or a total life of 33 months.

Excitation Improvement—Electronic Excitation and Regulation of Electric Generators as Compared to Conventional Methods

FELLOW AIEE

IN A period of four years in the early 1940's the writers gathered a background of exciter failure information, both on their own system and others, involving some 38 exciter failures. These failures caused shutdowns of generators having so-called conventional exciter units using both direct-connected and motor-driven commutating exciters, most with pilot exciter combinations driven from common shaft of main generator.

It was concluded that the entire exciter system was definitely not in accord with the ruggedness of design built into the turbogenerator. Whereas the turbogenerator could run for periods of two or three years without shutdown for service, the commutating-type exciter was not in this class and something should be done to improve this situation.

From these investigations it was determined that the weakest link in the excitation system was the pilot exciter as it is small and subject to vibration hazards. This was eliminated by the substitution of a permanent magnet pilot using stationary dry-type rectifiers or electronic rectifiers. Later two new machines, equipped with entirely new complete electronic systems, were put in service at the Warren Station of Pennsylvania Electric Company. A third unit with slightly revised layout now is being installed. This paper discusses the factors influencing the design and adaptation of this equipment and the field experience to date.

It is common knowledge that the rotating commutator and brush combination, to say nothing of the other components which go to make up an exciter system, is most vulnerable due to the fact that it could never be called upon to run long, continuous periods of time without shutdowns for servicing. Therefore it was the writers' intention in considering the designs for any improvement to be able to service vulnerable parts without shutdowns or affecting the generator output, and at the same time supply all spare exciter capacity necessary. It was firmly believed that the exciter and regulator performance could be improved by the use of electronic components, which had already proved themselves over long periods of time in other industrial applications.

Results of Investigation

As a result of investigation it was found that the frequency of exciter troubles, as well as the uncertainty of maintenance requirements, were due principally to the following causes:

1. Variation in brush structure and composition, even with so-called identical style brushes, and sometimes with brushes from the same batch.

2. The influence variation of current density on commutator performance.

3. Copper structure variation which led to commutator irregularities resulting in high bar and thermal instability.

4. Commutator bar slippage as affected by unusually high vibration causing brush skip due to high mica or commutator bar.

5. Commutator wear which required shutdown for proper correction.

6. Humidity variations.

7. Dust and dirt effect on brush wear and commutator cutting.

8. Banding failures due to overloading or mechanical failure.

9. Commutator riser failures.

10. Generator field circuit breaker failures due to contact corrosion when not operating over long periods of time.

11. Difficulties with parallel operation of exciters on common bus excitation system.

Although it was realized that steps have been taken to improve brush-type commutator machines, maintenance still cannot be completely accomplished while the unit is in operation. It was therefore felt that the electronic exciter offered the best possibility of eliminating most of the difficulties experienced.

Some of the other features considered favorable to the electronic exciter are the following:

1. Simplicity of the exciter alternator, its winding and installation, as compared to a d-c generator winding. Also the inherently smaller rotor and the total absence of banding, brush rig, risers, and commutator.

2. Electronic exciters could be a combination of all time tried equipment:

a. The alternator is generally acknowledged by everyone to be in this class.

b. The ignitron tubes have served for years and have replaced the rotating commutator generators in many places.

3. The complete freedom from system disturbances as would not be the case with separate excitation furnished by motor generator sets.

4. No spare excitation required.

5. Eliminates field circuit breakers and bussing with their inherent hazards.

6. No exciter paralleling problems.

Paper 50-51, recommended by the AIEE Power Generation Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30-February 3, 1950. Manuscript submitted October 31, 1949; made available for printing December 16, 1949.

A. H. Phillips is with Gilbert Associates, Inc., Reading, Pa., and W. H. Lambert and D. R. Pattison are both with the Pennsylvania Electric Company, Johnstown, Pa.

Permanent Magnet Pilot Exciter

Our first step in eliminating exciter troubles was to improve the pilot exciter. Since the pilot on the end of the shaft was subjected to occasional vibration and by reason of its size was not as stable as the main exciter, it was decided to use a 4-pole permanent magnet rotor and 3-phase stator to deliver 120-cycles to a stationary dry-type or electronic rectifier. A unit of this type was manufactured and placed on test for a period of eight months. It was subjected to all known hazards of short circuits and load variations, and was found to be a very stable machine. Another unit was manufactured to coincide with the mounting conditions for a 40,000-kw unit at the Seward Station for Pennsylvania Electric Company. This unit went into service in August 1947. Thus we have had approximately $2^1/_2$ years of experience with this pilot exciter.

During a scheduled shutdown for inspection and maintenance of the turbine approximately 15 months after the unit was put in service, a complete change of rectifier tubes was made but no tube replacements were made during that period. Several tubes had loose bases but this condition has been corrected in the tubes as now produced. During the initial operation of the unit it was apparent that tube life could be extended by preheating the filaments, so equipment providing automatic change-over to the station power supply was ordered and the installation made after 15 months operation of the original unit. In addition to prolonging tube life the change-over to the separate power source provides field current for a longer period during shutdown of the generator, also supplies an emergency power source for the rectifier, and is simpler and more reliable than a hand-operated circuit breaker or time delay circuit in the anode supply of the rectifier.

Since it was recognized that the pilot exciter was responsible for a large number of unscheduled shutdowns, temporary action was taken on several machines by Pennsylvania Electric Company as well as a large number of other utilities waiting experience on the new magnetic pilot. This temporary action was in the form of using a storage battery in place of the pilot exciter source and providing shaft extension for the application of the permanent magnet pilot at a later date.

Warren All Electronic Excitation and Voltage Regulation

When the excitation for the two 37,500-kva turbine-generator units for the new Warren Station was under consideration in 1944 it was felt advisable to review the possibility of a complete elimination of commutator-type exciters from the shaft of these two units. Also the possible elimination of all rotating commutator d-c machinery in this plant was the general keynote. The final result is that the only equipment of the rotating commutator type installed in this plant consists of a few small, reversible, positioning, and valve operating motors.

It also was felt that the electronic exciter, in addition to the features cited previously, would be superior in its response and ability to take overloads as full electronic excitation provides the only ideal medium for the application of electronic regulation, which also was to be a part of this excitation system. In contrast to the brush-type commutation, the electronic would have a much wider operating range for the electronic exciter can operate at very light loads or severe overloads for long periods of time without damage. In further consideration, if parallel operation was ever required this could be accomplished with simplicity and without the danger of feedback.

At the time the original electronic excitation system was proposed, the permanent magnet pilot was to be an integral part of the system as outlined in Figure 2. However, when the Warren plant units were laid out as shown in Figure 1, it was not included due to lack of actual field experience. It was finally conceded as superior in many ways as stated in the paper on Design and Test on Electronic Exciter by Colaiaco, Johnson, and Reilly.[1] As pointed out by them, it would provide an entirely separate low-voltage excitation unit for the main exciter. It is included in the new generator about ready for service at Seward Station of Pennsylvania Electric Company.

With the possibility of realizing complete electronic excitation for the Warren generators, steps were taken to exploit all the necessary details with the manufacturer. These details have been described in the aforementioned paper. Several small defects were discovered and remedied when the number 1 machine was put in service. Otherwise the operation has proved very satisfactory. The difficulties experienced were all of minor consequence and were to be expected in the initial product. The time required to correct them was amplified by the fact that the main generator had to be up to full speed before any adjustments or checking could be done on any exciter units. In the more recent unit for the

Figure 1 (below). Design and layout of first system installed at Warren Station

Figure 2 (right). Original design of electronic excitation system unit as being installed on Seward generator

Figure 3. Final layout of electronic excitation at Warren Station

Seward Station, a separate 3-phase supply from the station service can be used for checking prior to the time that the turbo-generator unit is ready for service. Although a rather remote possibility, a failure of the exciter alternator would not be too serious since the electronic rectifier can be supplied from any 3-phase source.

It is of interest to note that during the first week of operation of the number 1 generator at Warren plant a gaseous ignitron tube was discovered. This condition was not previously detected because the tubes were not check tested after shipment. It is significant that this tube section was immediately isolated and the tube replaced while the generator was in full load operation. Due to the fact that the rectification is removed from the shaft, no shutdowns were required in the following $1^1/_2$ years of operation. Contrasted with this maintenance and during the same period a similar generator, with brush-type commutation direct connected exciter, had to be completely shut down to make necessary repairs to a high bar on its commutator. There were, however, during the $1^1/_2$ year period three arc backs registered, but no one knows when they occurred as they were automatically cleared and reclosed with no disturbances to the generator or the system.

Although we expected some additional cost on this type of excitation system compared to the conventional commutator exciter system, the actual difference in over-all plant costs amounts to very little. The separate excitation is inherently built into each electronic unit and the anode circuit breakers, which can be operated at will, completely supplant the conventional field circuit breakers. Other items not required are the field rheostat, high speed contactors, field cubicle, busses, supply circuit breaker for spare exciter set, spare exciter, conduit, and cables. For comparison, considering a similar two generator station equipped with two 40,000-kva units, the cost of the miscellaneous equipment necessary in conjunction with the conventional excitation and including a spare exciter shows less than ten per cent difference in actual over-all exciter cost.

As indicated previously, the electronic exciter for the new 50,000-kva unit at Seward is being installed as shown in Figure 2. In this arrangement the permanent-magnet type 3-phase pilot is to produce essentially a fixed field on the exciter alternator and through a selenium rectifier rather than the electronic rectifier. The change to the selenium rectifier was felt advisable due to its excellent record in similar low power applications and it is thought it eliminates possible tube troubles.

The shaft-driven exciter alternator in this case is a standard 3-phase unit which supplies power to the rectifier unit through a 3-phase to 6-phase transformer. This arrangement allows the use of standard equipment rather than a special 6-phase alternator as used in the Warren units. At the same time it introduces additional flexibility, as pointed out previously. This arrangement would permit supplying the rectifier transformer from the station service bus for prechecking, preheating, and so forth. In the event of emergency or failure to the exciter alternator it would still maintain excitation on this unit although not entirely separate from system disturbances.

Some special training of the operators for the Warren units was necessary but there were no actual troubles experienced. After a thorough explanation of the new exciter principle, the operators were put through a few trial runs in which they were required to handle the controls. They very quickly became familiar with the control operation and the flexibility inherent in its design. We wish to stress the point brought out in the paper by Colaiaco, Johnson, and Reilly[1] for they have shown a number of oscillograph tests conducted from data collected from the test floor, that is, the ability of these machines to ride out system disturbances. In actual service they seem far superior in their stability and much more readily adjust themselves to operating conditions than the older style excitation.

At the end of the 1-year period, the Warren generator was taken down on a prescheduled date for general inspection of turbine and auxiliaries. At this time no changes were made to the tubes or other electronic equipment except that the anode electrolysis targets in the main rectifier cooling system were replaced, having lost approximately one-half of their active material in the 1-year period. We do not expect to make any over-all tube replacements on a periodic basis in these exciter systems as there is inherently sufficient capacity to allow for tube failures without affecting generator output or performance.

Conclusions

1. Flexibility of operation and range of control are inherently a part of the electronic exciter voltage regulator combination.
2. Electronic regulation is most effective when coupled with electronic excitation system and provides high speed regulation.
3. Reserve capacity built in requiring no extra excitation source.
4. Excitation system entirely separated from system disturbances.
5. Ease of maintenance at comparatively low cost.
6. Comparable first costs compared to the over-all exciter application.
7. No feed-back problems.
8. No field circuit breaker maintenance troubles as any anode circuit breaker can be taken out of service for maintenance or inspection at any time.
9. Capable of long periods of operation without shutdown of main generator.

Discussion

J. H. Kinghorn and **F. M. Porter** (American Gas and Electric Service Corporation, New York, N. Y.): In our paper of 1946 entitled The Development of Modern Excitation Systems for Synchronous Condensers and Generators,[1] we related our experience with 15 exciter applications. These included four

direct-connected main exciters with electronic pilot exciters, three synchronous condensers with electronic main exciters, and six direct-connected exciters with amplidyne controls. All of these have electronic regulators.

We pointed out at that time that 47 machine years of operation with electronic pilot exciters and 29 machine years of operation with electronic main exciters had demonstrated the excellent performance and reliability of this type of excitation. Since then we have experienced four more years of satisfactory performance on all of these units, making the operation to date 63 machine years for electronic pilot exciters and 41 machine years for full electronic exciters.

Also, the 87 machine years of satisfactory electronic regulator performance on these units, experienced as of 1946, have increased to 143 machine years. Therefore, we have every reason to believe that very satisfactory results will be obtained from the electronic features of the new excitation arrangements described by Phillips, Lambert, and Pattison.

Further analysis of tube failures for the past four years has been made for the three electronic main exciters. It is found that thyratron tube life has shown slight improvement over this period, the average service hours per tube failure being 13,650. Ignitron tube life has doubled from the previous 16,340 hours per tube failure to 32,680 hours. Furthermore, one exciter has operated for the entire four years without an ignitron failure and all of its tubes now have been in service for $7^1/_2$ years. However, in general the foregoing figures indicate that expenditures for tube replacement still are an appreciable item in maintenance costs.

As pointed out in our 1946 paper, we also have found that the performance of the amplidyne control system with direct-connected exciters has been essentially equal to that obtained from the electronic main or electronic pilot exciter applications. The authors state that the installation of the electronic exciter is about 10 per cent more costly than a single direct-connected exciter plus a spare exciter. However, when several generators are involved, as is frequently the case, the cost of one spare exciter is spread over several machines and therefore the installed cost per generator is reduced. The additional cost of extra equipment in the electronic exciter such as ignitron tubes, power transformer, and heat exchanger, is readily apparent. Because the direct-connected exciter with amplidyne control results in a simpler and more economical arrangement, and, practically speaking, provides high speed and accurate voltage regulation equivalent to that of the electronic scheme, we are utilizing it on four large turbogenerators recently placed in service and on eight more generators to be installed in the next three years.

We cannot agree that the direct-connected exciter is the unreliable piece of equipment that has been stated. We would be interested in knowing the age of the generators and exciters involved in the 38 exciter failures as an aid in evaluating design improvements. Our own experience with direct-connected exciters over a period of approximately 30 years has been quite satisfactory. This includes 23 units in service for 25 years or longer, and 18 additional units installed since 1936. We have had the usual amount of brush and commutation troubles but these have not been too serious. Obviously exciters, the same as other equipment, require maintenance and repairs and eventually rewinding and replacement of some parts, particularly commutators. We have found it possible to take care of grinding commutators and other major repairs during shutdowns for turbine or generator maintenance. In most cases we have a motor-driven exciter set or sets which serve not only for emergency use in case of trouble with the direct-connected exciter but also in many cases for simultaneous starting of two generators involved in cross-compound units. The emergency shutdowns may be required for many reasons other than exciter trouble. This is particularly the case for power generation unit installations where there is one boiler, one turbogenerator with accessory equipment, all entirely independent of other units at the same plant. As far as the system of the American Gas and Electric Company is concerned, it is designed and operated so that any turbogenerator unit can be shut down for emergency repairs without affecting service from the system.

We conclude by stating that we believe the scheme described, utilizing direct-connected alternator with electronic excitation and regulation is another excellent and reliable arrangement for obtaining high-speed accurate voltage regulation and response for a turbogenerator. However, we also feel that based on many years of experience, the direct-connected exciter has proved to be a reliable piece of equipment, particularly with the design improvements that have been made in the last ten years. It is our opinion that the excitation scheme utilizing direct-connected exciter with amplidyne control is for all practical purposes just as good an arrangement, insofar as high-speed and accurate voltage regulation are concerned, and also that it results in a simpler and more economical installation.

A. H. Phillips, W. H. Lambert and D. R. Pattison: I wish to thank Kinghorn and Porter for their discussion. They certainly have brought out revealing facts regarding the reliability of electronic excitation, together with their valuable experience in the operation of such equipment.

I would like to make one comment on the cost, that is, where they referred to the statement in our paper that the cost is 10 per cent more than the cost of a single exciter plus a spare, and so forth. This is not exactly the comparison we made, as our 10 per cent cost value is based on a 2-unit plant. My personal feeling is that there should not be any additional cost in new excitation as it is simply a matter of production and application. If anything, in the long run the electronic excitation should be cheaper than the so-called conventional types.

I cannot connect statement of Kinghorn and Porter that any type of amplidyne control can be simpler or more economical, nor can it compare in speed of regulation. It still uses a multiplicity of commutators and brushes and we are sure it could not be as reliable, nor would it have spare excitation built in.

Refer to Mr. Langstaff's discussion of a previous paper[1] on electronic excitation versus conventional types. In regard to the accessibility of the equipment for repairs while under load, we have worked on this equipment (practically every part of it including tube changes, water pump repairs, and anode circuit breaker adjustments) while the machine was carrying full load.

The Thermal Resistance Between Cables and a Surrounding Pipe or Duct Wall

F. H. BULLER
MEMBER AIEE

J. H. NEHER
MEMBER AIEE

ONE step in the calculation of underground cable temperatures involves the determination of the temperature rise of the cable surface above the immediately surrounding inclosure such as a duct structure or a gas- or oil-filled pipe. Since the intervening medium is a fluid, the mode of heat transfer simultaneously involves convection, conduction, and radiation.

The semiempirical methods now in use for this determination in the case of cables in duct are not entirely satisfactory, and with the advent of gas- or oil-filled pipe-type cables there has arisen a definite need for a method of evaluation for these cable types as well.

Because of the complex nature of the problem and the number of independent variables which are present, it is impractical to cover completely all possible combinations which may be met within practice solely by tests. By developing a theoretical relationship between the variables, however, it is possible to develop procedures by which the test data available may be analyzed in such a way that relatively simple working expressions may be derived which may be applied with sufficient accuracy over the entire working range.

The theoretical relationship for the case of cables in duct was recently presented in a paper by one of the authors.[1] In the present paper this relationship has been extended to cover oil and gas pipe systems as well, and from the test data presented the requisite working expressions for thermal resistance or surface resistivity factors have been obtained.

Theoretical Considerations

The theoretical relationships given in Appendix II of reference 1 for the case of cables in duct have been expressed more completely to account for the physical characteristics of the media involved in Appendix I of this paper. The resulting equations for the the thermal conductivity between cable and duct or pipe with air or gas as the intervening medium are

$$\frac{Q}{\Delta T}(\text{gas}) = \frac{0.092\ D_s'^{3/4}\Delta T^{1/4}P^{1/2}}{1.39+D_s'/D_d} + \frac{0.0213}{\log_{10}D_d/D_s'} + 0.102D_s'^4(1+0.0167T_m)$$

watts per degree centigrade foot (1)

and with oil as the medium

$$\frac{Q}{\Delta T}(\text{oil}) = \frac{0.053D_s'^{3/4}\Delta T^{1/4}T_m^{1/2}}{1.39+D_s'/D_d} + \frac{0.116}{\log_{10}D_d/D_s'}$$

watts per degree centigrade foot (2)

For a single cable $D_s' = D_s$, the diameter of the cable. For three cables in the pipe or duct it is customary to base D_s' on the circumscribing circle of the cables in triangular configuration, $D_s' = 2.15\ D_s$. For two cables the relationship $D_s' = 1.65\ D_s$ is satisfactory.

It will be noted that the primary variable in equation 1 is D_s'. As a result, subsequent analysis and development will be facilitated if this equation is written in the equivalent form

$$\frac{Q}{D_s'\Delta T} = \frac{0.092\,\Delta T^{1/4}P^{1/2}}{D_s'^{1/4}(1.39+D_s'/D_d)} + \frac{0.0213}{D_s'\log D_d/D_s'} + 0.102_s(1+0.0167T_m)$$

watts per degree centigrade foot inch (1A)

From the method of derivation which assumes a coaxial arrangement of the cable within the duct or pipe, the numerical constants of the first two terms of equations 1, 1(A), and 2 must be considered as being approximate only. They will serve, however, to evaluate the relative magnitudes of the terms, and the corresponding values finally employed will be based on test data.

As a practical matter, a high degree of accuracy is not required since the thermal resistivity between cable and duct or pipe represents a relatively small part of the total thermal circuit, and we are justified in materially simplifying these equations. From the standpoint of analysis of the test data and the subsequent development of working expressions, it is desirable to utilize the simple linear relationship

$$y = ax + b \qquad (3)$$

where y and x are variables and a and b are constants. Equations 1 and 2 are of this form provided that the second (conduction) and third (radiation) terms may be considered as constants within the desired accuracy of the final result. Considering equation 1A the conduction term constitutes about 14 per cent of the total in the case of a typical cable in duct installation, and about 8 per cent for a typical gas-filled pipe-type installation at 200 pounds per square inch. The corresponding values for the radiation term are 63 and 43 per cent.

Normal variations in D_s'/D_d may produce considerable variation in the conduction term, but the effect on the overall picture is small, because conduction is such a small part of the total heat flow. Variations of T_m can affect the radiation term by as much as 20 per cent over a sufficiently wide operating range; however, when calculating a cable rating, with a fixed copper temperature of the order of 70 degrees to 80 degrees centigrade, the range of this variable is very small, and an accuracy of the order of 3 per cent to 5 per cent may be expected.

In the case of equation 2, the conduc-

tion term constitutes about 24 per cent of the total for a typical oil pipe installation. Variation is more important than is the case with the gas-pipe cable, but is still within tolerable limits.

One peculiar phenomenon has been observed. The ratio of D_d/D_s', which appears in the conduction term also, appears in the first (convection) term of equations 1 and 2 but in such a way that a change in this ratio produces an opposite, though lesser, effect on the total value of these equations. A minimum error should, therefore, prevail when the conduction term is treated as a constant if the denominator of the convection term also is treated as a constant. This procedure will simplify the convection term but it will have the effect of approximately halving its numerical constant as compared with equations 1 and 2 since the numerical value of the denominator omitted is in the order of two. Actually the test data was analyzed both with and without this simplification, and no apparent change in consistency in the results was observed.

Analysis of Test Data

It follows from the preceding discussion that the test data for cables in duct and for gas-filled pipe-type installations may be analyzed by plotting the observed values of

$$y=\frac{Q}{D_s'\Delta T};\quad \text{against } x=\frac{\Delta T^{3/4}P^{1/3}}{D_s'^{1/4}} \qquad (4)$$

The data given in Table I were compiled from tests on gas-filled pipe-type cable systems by The Detroit Edison Company,[3] the General Electric Company, and the General Cable Corporation. These data are plotted in Figure 1 and the values of a and b in equation 3 are established as $a=0.070$; $b=0.20$.

Table II presents similar data for cables in single dry fiber and Transite ducts in concrete taken from the Barenscher[4] and Johns Manville tests discussed in reference 1. These data also are plotted in Figure 1 where it will be seen that the Transite duct points fall on the gas in pipe curve, but the fiber duct points result in a different curve having the same value of $a=0.07$ but $b=0.10$. This difference may be explained by the fact that the duct wall departs from an isothermal as a result of the relatively high thermal resistance of the materials used, that of the dry fiber being considerably higher than that of the transite.[1]

The test data for oil-filled pipe-type cable systems from tests by The Detroit Edison Company,[3] the General Electric Company, and the Okonite Company are presented in Table III and plotted in Figure 2. In this case, the analysis has been made by plotting the observed values of

$$y=\frac{Q}{\Delta T};\quad \text{against } x=D_s^{3/4}\Delta T^{3/4}T_m^{3/4} \qquad (5)$$

and results in the values of $a=0.025$ $b=0.60$ in equation 3.

It will be seen from the analysis of the test data that the agreement between theoretical and observed numerical constants of the simplified convection term is extremely good in the case of oil as the medium, but in the case of gas, the observed value of 0.07 is somewhat higher than the expected value of about 0.046. This is rather surprising since tests number 2 (with gas) and number 9 (with oil) which are consistently close to the established curves in Figures 1 and 2 were made with the same physical setup which remained unchanged throughout the tests except for the change in the media employed. Therefore, we should expect the ratio of values obtained to be the same as the ratio of the numerical constants of the convection terms in equations 1 and 2.

This discrepancy seems to be due to the fact that in the case of several cables within the pipe, a condition of the majority of test data, there is an additional circulation of the gas between the cables themselves which is not properly accounted for by the use of an equivalent diameter for the three cables, but which is apparently not effective when a more viscous medium such as oil is employed.

As indicated before, however, a high degree of accuracy is not required, and it is

Table III. Test Data on Oil-Filled Pipe-Type Cable Systems

				34.9	11.7	48	2.98	133

felt that a working expression based on the foregoing analysis will be sufficiently accurate.

Working Expressions

In formulating the thermal resistance between cable and duct, it is customary to express this resistance in terms of an equivalent surface resistivity factor, assuming that the entire resistance was concentrated at the cable surface, according to the expression

$$H_{sd}=0.00411\,\frac{\beta}{D_s'}\ \text{thermal ohm feet} \qquad (6)$$

in which β is expressed in degrees centigrade square centimeters per watt. Since $H_{sd}=\Delta T/Q$ it follows from equation 6 that

$$\beta=243\,\frac{D_s'\,\Delta T}{Q}\ \text{degree centigrade centimeter per watt} \qquad (7)$$

and

$$\Delta T^{1/4}=0.253\,\frac{\beta^{1/4}Q^{1/4}}{D_s'^{3/4}}\ (\text{degrees centigrade})^{1/4} \qquad (8)$$

It is thus possible to develop working expressions in terms of β in the case of cables in duct- or gas-filled pipe by substituting equations 7 and 8 in equations 3 and 4 with the appropriate values of a and b. In the case of oil-filled pipe a simpler expression is obtained in terms of H_{sd}.

For cables in single dry fiber ducts

$$\beta=\frac{13{,}700}{\beta^{1/4}\left(\frac{Q^{1/2}P}{D_s'}\right)^{1/2}+5.7}\ \text{degrees centigrade square centimeters per watt} \qquad (9)$$

For cables in other types of single dry ducts and in gas-filled pipe

$$\beta=\frac{13{,}700}{\beta^{1/4}\left(\frac{Q^{1/2}P}{D_s'}\right)^{1/2}+11.3}\ \text{degrees centigrade square centimeters per watt} \qquad (10)$$

For cables in oil-filled pipe

$$H_{sd}=\frac{40}{H_{sd}^{1/4}(QD_s'^2T_m^3)^{1/4}+24}\ \text{thermal ohm feet} \qquad (11)$$

The value of β from equations 9 and 10 is plotted in Figure 3 as a function of $(Q^{1/2}P/D_s')^{1/2}$ and the value of H_{sd} from equation 11 appears in Figure 4 as a function on $(QD_s'^2T_m^3)^{1/4}$. Also indicated on these figures are the values of these parameters for typical conditions.

In the case of cable in fiber duct, the thermal resistance of the duct wall is appreciable and should be accounted for. This is most readily accomplished by modifying equation 6 to include this resistance. Thus

$$H_{sd}'(\text{fiber})=0.00411\,\frac{\beta}{D_s'}+0.33\ \text{thermal ohm feet} \qquad (12)$$

in which the second term represents the difference in thermal resistance between a 4-inch fiber duct and the corresponding section of concrete which it replaces.

Discussion of Values for Cables in Duct

It will be seen that the method of determining the thermal resistance between cable and duct presented herein differs somewhat from the method given in reference 1, although the results are substantially the same for terra cotta and fibre ducts. For Transite ducts, the values of thermal resistance derived in a more fundamental manner in the present paper, are slightly lower than those appearing in the reference, being equal to those assumed for terra cotta.

It will be recalled that the reasoning used in developing algebraic expressions for these values assumes an isothermal duct wall. The test data presented in

Figure 1. Analysis of test data for cables in duct- and gas-filled pipes

Table II and plotted in Figure 1, however, indicate a good correlation even where there is substantial deviation from the assumed isothermal as indicated by the basic data on which the table is based. Within the range covered by the data, increasing the departure from the isothermal changes the resulting constants somewhat but does not invalidate the method of analysis.

It follows therefore that a considerable variation in β for cables in single-fibre ducts may be expected depending upon the relative thermal resistivities of the duct wall and the surrounding medium, and other data which has come to the authors' attention confirms this. Thus the curve of Figure 3 for fibre duct should be considered as an upper limit.

Similarly, the application of the values given for single ducts to the case of cables in a multiduct structure, depends upon the effect which the total heat field has in further changing the temperature gradients around the individual duct walls. The data given by Smith in his discussion of reference 1 indicates a value of β for multiple-fiber ducts in concrete corresponding closely to the curve for cable in pipe.

As indicated in reference 1, additional test data taken on multiple-duct assemblies are desirable to definitely establish the limits under these conditions.

For reasons also indicated in reference 1 these values are not directly comparable to the values adopted by the Insulated Power Cable Engineers Association[6] and are not directly adaptable to their calculation procedure.

Conclusions

1. The theoretical relationships between the various quantities involved in the effective thermal resistance between cables and a surrounding single duct or pipe have been developed in a manner which properly accounts for the simultaneous modes of heat transfer by convection, conduction, and radiation.

2. By means of these relationships certain test data on cables in duct and in gas- and oil-filled pipes have been analyzed and working curves are presented for determining the thermal resistance for any particular case which may be encountered in practice.

3. Under typical conditions representative values of the equivalent surface resistivity factor β for use in equation 6 are 800 degree centigrade square centimeters per watt for cables in pipe, single dry terra cotta or transite ducts at atmospheric pressure, 450 for cables in gas-filled pipe-type installations at 200 pounds per square inch, and 350 for cables in oil-filled pipe-type installations. Representative values of β for cables in single dry fiber ducts will vary from 850 to 1,100.

Figure 2. Analysis of test data for cables in oil-filled pipe

Appendix I. Theoretical Development of Thermal Conductivity between Concentric Isothermal Cyclinders with Gas or Oil as the Intervening Medium

The mechanism of heat transfer between a cylindrical radiator and an enveloping isothermal enclosure through an intervening fluid medium is such that a portion of the total heat flow Q is carried by convection Q_{cv}, a portion by conduction Q_{cd}, and the remainder by radiation Q_r. In formulating the components of the thermal circuit, therefore, it is more convenient to work in terms of thermal conductances rather than thermal resistances since the former quantities are directly additive. Thus, if ΔT is the temperature drop in degrees centigrade across the circuit

$$\frac{Q}{\Delta T}=\frac{Q_{cv}}{\Delta T}+\frac{Q_{cd}}{\Delta T}+\frac{Q_r}{\Delta T} \text{ watts per degree centigrade foot} \quad (13)$$

The phenomenon of convection involves the conception of the temperature drop being concentrated in two films, one at the surface of the cylindrical radiator of diameter substantially equal to the diameter of the radiator D_1 in inches, and one at the surface of the enclosing isothermal surface which will be considered also being cylindrical of diameter D_4. The following formula based on McAdams[3] (equation 42, page 251, 1st edition only) is applicable to either film.

$$Q_{cv}=122D_f^{5/4}\Delta T_f^{5/4}K \text{ watts per foot} \quad (14)$$

in which D_f is in inches, and

$$K=\left(\frac{\beta^2 C_p g\, e}{\mu\ \rho^2}\right)^{1/4} \text{ watts per centimeter}^{7/4} \text{ degrees centigrade}^{5/4} \quad (15)$$

The significance of the components of equation 15 and representative values for gas (air or nitrogen) and Suniso number 6 oil are given in Table IV.

Figure 3 (left). Values of β for cables in dry single ducts and gas-filled pipe

Figure 4 (above). Values of H_{sd} for cables in oil-filled pipe

In the case of air or inert gas, these physical properties are substantially independent of temperature over the working range but the density is a direct function of the pressure. Thus, if P represents the pressure in atmospheres, from equation 15

$$K_g = 0.000755P^{1/2} \text{ watts per centimeter}^{7/4} \text{ degrees centigrade}^{5/4} \quad (16)$$

When oil is employed as the medium the physical constants are substantially independent of pressure and temperatures with the exception of the viscosity which for the type of oil commonly employed (Suniso number 6) may be taken as varying inversely as the cube of the temperature according to the relationship

$$\mu_0 = \frac{94{,}000}{T_m^3} \text{ grams per centimeter second} \quad (17)$$

The value of K for oil thus becomes

$$K_o = 0.000434T_m^{5/4} \text{ watts per centimeter}^{7/4} \text{ degrees centigrade}^{5/4} \quad (18)$$

The solution of equation 14 for the two films in series and with equation 16 or 18 substituted therein is given with sufficient accuracy by the expressions

$$\frac{Q_{cs}}{\Delta T}(\text{gas}) = 0.092\frac{D_s^{3/4}\Delta T^{1/4}p^{1/2}}{1.39+D_s/D_d} \text{ watts per degree centigrade foot} \quad (19)$$

$$\frac{Q_{cs}}{\Delta T}(\text{oil}) = 0.053\frac{D_s^{3/4}\Delta T^{1/4}T_m^{5/4}}{1.39+D_s/D_d} \text{ watts per degree centigrade foot} \quad (20)$$

From a theoretical standpoint the expression for the conduction component should take into account any eccentricity between the cylindrical radiator and the enveloping isothermal enclosure. In the practical case of cables in duct or pipe the cables will not rest uniformly on the bottom of the duct, and also in the case of a nonmetallic duct the duct wall is not strictly maintained as an isothermal. Since these effects cannot be evaluated, the familiar expression for the resistance between two concentric cylinders in terms of the dimensions of the cylinders and the thermal resistivity of the medium will be used. Thus

$$\frac{Q_{cd}}{\Delta T}(\text{gas}) = \frac{0.0213}{\log_{10} D_d/D_s} \text{ watts per degree centigrade foot} \quad (21)$$

$$\frac{Q_{cd}}{\Delta T}(\text{oil}) = \frac{0.116}{\log_{10} D_d/D_s} \text{ watts per degree centigrade foot} \quad (22)$$

The radiation component with gas as the medium is given with sufficient accuracy by the following expression based on McAdams[3] equation 5, page 61, first edition

$$\frac{Q_r}{\Delta T}(\text{gas}) = 0.102D_s\epsilon(1+0.0167T_m) \text{ watts per degree centigrade foot} \quad (23)$$

in which ϵ is the emissivity coefficient of the surface of the cable and T_m is the average temperature of the medium. The radiation term is ineffective when oil is the medium.

The over-all thermal conductivity is obtained by substituting equations 19, 21, and 23 or equations 20 and 22 in equation 13.

D_d = inside diameter of the duct wall or pipe in inches

T_m = average temperature of the medium in degrees centigrade

ϵ = coefficient of emissivity of the cable surface

x and y = rectangular coordinates

a and b = experimentally determined constants

H_{td} = thermal resistance between equivalent sheath and duct wall or pipe in thermal ohm feet

H_{td}' = equivalent thermal resistance between equivalent sheath and fibre duct wall including the increased thermal resistivity of the duct wall over that of the surrounding medium in thermal ohm feet

β = equivalent surface resistivity factor in degrees centigrade square centimeters per watt

ρ = thermal resistivity in degrees centigrade centimeters per watt

μ = average absolute viscosity in grams per centimeters second

δ = density in grams per cubic centimeter

C_p = specific heat at constant pressure in watt seconds per degree centigrade gram

g = acceleration due to gravity in centimeters per second squared

e = thermal coefficient of expansion in centimeters per centimeter degree centigrade

K = a factor dependent upon the physical constants of the medium in watts per centimeter$^{1/4}$ degrees centigrade$^{5/4}$.

Discussion

R. H. Norris and Mrs. B. O. Buckland (General Electric Company, Schenectady, N. Y.): Efficient work in the heat-transfer field on a variety of applications requires awareness of the definitions and units, in order to avoid confusion and misunderstanding. In this paper and other papers written by cable engineers, confusion arises as to the exact meaning of the expression "thermal resistivity." Resistivity as normally defined (by the American Standards Association (ASA) for example) is a property of a substance and is not affected by its geometry; for example, the resistivity of copper has a constant value at any specified temperature, while its resistance depends on its size and shape. Then the use of the word "resistivity" for surface phenomena is a misuse of the term.

To show how the distinction between resistance and resistivity enters into the picture, the thermal circuit for a single-conductor cable in air is given in Figure 1 of the discussion.

In this figure, t_{cu}, t_{sh}, and t_a are temperatures of copper, sheath, and ambient, respectively, δ is insulation thickness, ρ is thermal resistivity of the insulating material, A_L is the log mean area of the insulation for heat flow, A_{sh} is sheath area, and β_c and β_r are the cable engineers' terms for "surface resistivity" for free convection and radiation. Each fraction in the Figure is the thermal resistance; and when resistances and temperatures are known, the heat dissipation of the cable is known. But in order for the resistances to be dimensionally consistent, the dimensions of ρ must be different from the dimensions of β, and therefore ρ and β should not be called by the same name.

Since the definition of ρ as thermal resistivity conforms to ASA standards, it might be better to denote β as thermal resistance of a unit surface. Its reciprocal h, is defined as surface heat transfer coefficient, or alternatively as surface film conductance. The concept of conductance is particularly applicable here, as the total film conductance is the sum of h_r and h_c, and therefore numerically easier to handle.

The units of length used in the paper seem to be a mixture of metric and engineering units. A combination of square centimeters with feet has no logical basis. If any cable dimensions were expressed in centimeters, the mixture would be logical although not standard; but since dimensions are not so expressed, it seems time to abandon this practice and use the engineering system of units throughout.

It is therefore proposed that the AIEE Committee on Insulated Conductors take steps to persuade its adherents to become familiar with ASA standards and to use them where they apply.

R. W. Burrell (Consolidated Edison Company of New York, Inc., New York, N. Y.): The authors have presented a desirable elaboration of Appendix II of a previous paper by Mr. Neher.[1] Although the approach to the problem is not changed, the material presented in the Appendix referred to is of sufficient importance to justify a more detailed presentation.

It is apparent to those engaged in the field of cable heating that the Insulated Power Cable Engineers Association recommended value of β, while perhaps sufficiently conservative for general design, lacks the flexibility needed in comparing alternative constructions. Precise determinations of β for various types of installations may not be possible because of inherent variations in the physical constants involved; however, as additional test data are compiled, the

Figure 1. Thermal circuit for single conductor in air

probable range of β, for a particular case, will be better understood, thereby making possible more realistic comparisons. The authors clarify our conception of the effect of the various parameters involved in the temperature drop between cable surface and duct or pipe wall. For a given system of cables in duct or pipe, the thermal resistance will decrease sensibly with increasing watts loss.

W. B. Kirke[3] introduced this modification which is taken into account in determining cable ratings for the Consolidated Edison system.

As one follows the assumptions made in this paper, there appear various points to which exception might be taken on the ground that they are not substantiated, for example: the assumption of the same constant in the expression for the convection film at the cable surface and at the inner duct wall, the treatment of conduction on the basis of a concentric system, and the arbitrary assumption of an emissivity coefficient of the cable surface of 1.0. Yet, the important point is that putting all of these various assumptions together in the particular form given in the paper, the over-all end result does produce expressions which are reasonably satisfactory.

It is unfortunate that, while the basic equations and the selection of parameters have a reasonably sound theoretical basis, the final working expressions given are essentially empirical and do not allow an accurate determination of the separate effect of the three modes of heat transfer. On the average, the calculated values of $Q/\Delta T$ for the oil-filled pipes, gas-filled pipes, and cable in duct are about 5 per cent, 15 per cent, and 55 per cent higher, respectively, than the measured values given in Tables I, II, and III of the paper. Specialists in the field of cable heating would be interested in knowing which component or components are responsible for these discrepancies so that extrapolation into new fields could be made with confidence.

It is stated in the paper that the agreement between theoretical and empirical numerical constants of the simplified convection term is close for the case of an oil medium, but is off appreciably for the case of a gas medium. It also can be said that the conduction-radiation constant agrees with theory for the case of a gas medium; however, for the case of an oil medium, the constant theoretically appears to range from 0.60, as given in the paper, to nearly twice that value, depending upon the values of D_i' and D_d involved.

From the over-all standpoint, it nevertheless appears that the expressions for β and H_{td}, as given in equations 9, 10, and 11 of the paper are quite workable and agree with test data as well as could reasonably be expected. A high degree of accuracy in the calculation of allowable current ratings of cables is not yet to be expected but important work has been done in the past few years in clarifying our understanding of heat flow through duct structures and the earth, and this paper is an important contribution to such understanding.

R. J. Wiseman (The Okonite Company, Passaic, N. J.): I like the author's paper very much. It explains the three methods of heat flow from a cable to a surrounding medium, namely, conduction, convection, and radiation. Also, they give the various parameters which influence each factor namely, cable diameter, temperature, and temperature difference, and viscosity of the medium. The various formulas look quite formidable when we note terms raised to fractional powers. It is not easy to obtain the constants for each formula as they are dependent on conditions not easily calculable so it is necessary to get test data and work back to numerics which will give the desired results. It so happens that as all three modes of heat transfer are functioning at the same time, a change in dimensioning tends to work in opposite directions, reducing thereby the effect of diameter. Also the range in temperature is not great and as we take the one-fourth power of temperature difference and three-fourths power of temperature, the variation with temperature is not great.

About two years ago we decided to restudy the thermal constants we obtained when we originally set up the Oilostatic cable system. At that time we used the cylindrical log formula of ratio of internal pipe diameter to circumscribed circle over the assembled conductors, and also a constant which was a function of the temperature.

Our more recent tests showed that the thermal resistance was almost independent of temperature (a variation of about 10 per cent between 30 and 61 degrees centigrade) for an oil pressure zone and a very few per cent for a gas pressure zone at 200 pounds per square inch. We also noted that within the accuracy of testing we could safely assume the thermal resistance to vary as inversely as the diameter of the shielding tape over the insulation. As a result, we have set up two simple formulas for the determination of the thermal resistance of the pressure zone for three cables in a pipe, namely, for oil-pressure system $H=1.60/D$ thermal ohms per foot per conductor where, D is the diameter in inches over the shielding tape; and $H=2.58/D$ thermal ohms per foot per conductor for a gas pressure zone operating at 200 pounds per square inch. You will find these values of thermal resistance for the pressure zones amply accurate.

As the authors refer to the surface resistivity factor β, the values of β comparable to the above constants in $H=0.00411\ \beta/D$ are $\beta=390$ for an oil-pressure system as compared to 350 given by the authors and $\beta=627$ for a gas-pressure system at 200 pounds per square inch as compared to 450 given by the authors. We are quite confident in our values and have been using them for over a year.

Paul Greebler (Johns-Manville Corporation, Manville, N. J.): In this paper the authors have contributed immensely toward an understanding of the mechanisms of heat transfer from the cable to its surrounding pipe or duct wall. The theoretical analysis was necessarily based upon the simplifying assumption of a coaxial cable in duct arrangement. This does not, however, detract from the value of the analysis given in the paper, since this analysis gives the order of magnitude contributed by each of the three mechanisms of heat transfer.

The authors have assumed for cable in duct that the component of the thermal conductivity due to radiation can be treated as a constant in the range of normal operating temperatures. Only the component due to convection was considered as variable with changing cable diameter and heat flow. This assumption does not lead to a true picture of the variation in thermal resistivity with heat flow, or more fundamentally, with cable temperature. Mr. Barnett and I have stated in our paper[1] that the decrease in thermal resistivity with increasing sheath temperature is caused primarily by variation in the radiation component of heat transfer, and that the effect of temperature variations on convection are negligible over the normal operating range. This statement is verified by calculations based upon equation 1A of the Buller-Neher paper, which is repeated here:

$$\left(\frac{Q}{D_s'\Delta T}\right)=\underbrace{\frac{0.092\,\Delta T^{1/4}\rho^{1/3}}{D_s'^{1/4}(1.39+D_s'/Dd)}}_{\text{(convection)}}+\underbrace{\frac{0.0213}{D_s'\log D_d/D_s'}}_{\text{(conduction)}}+\underbrace{0.102\epsilon(1+0.0167T_m)}_{\text{(radiation)}} \qquad \text{(1A)}$$

in watts per degree centigrade foot inch. The emissivity factor, ϵ, is assumed to be unity at atmospheric pressure.

Table I of the discussion lists two representative sheath temperatures from our test data on fiber duct in concrete, and these temperatures might very well be representative of the operating range of a cable. The term $(Q/D_s'\Delta T)$ evaluated in equation 1A is inversely proportional to the surface resistivity factor, β.

The three terms in the equation give the thermal conductivity components due to convection, conduction, and radiation respectively. As we increase the sheath temperature over the range shown, the increase in the radiation term produced by substituting our experimental data in the Buller-Neher equation is five times greater than that of the convection term. This shows that the experimentally observed decrease in β over this range is due almost entirely to the increase in the radiation term. These calculations are based, of course, on the rather large cable size that we employed in our tests. A smaller cable size will increase the effect of the convection term only slightly, however, and not nearly enough to make its variation with temperature equal to that of the radiation term. Identical calculations with our data on Transite in concrete, Transite in air, and fiber in air, show similar relative variations in the radiation and convection terms.

The authors have neglected the variation in radiation component of conductivity with temperature, pointing out that these variations are quite small. This is justifiable from a practical standpoint. However, the variations in the convection component with temperature also should be neglected for practical considerations, since, as is shown in Table I of the discussion this factor is even smaller than the change in the radiation term. This would considerably simplify the Buller-Neher equations for the surface resistivity factor. In their equations 9 and 10, the surface resistivity factor, β, depends upon the fourth root of the heat flow. This does not have much significance since it is based upon the variation in the convection term, a second order effect compared with the radiation term. Similarly the dependence of β upon the square root of the sheath diameter is doubtful, since the change from a fourth root to a square root dependence in the convection term also was based on the very small change in convection conductivity with temperature.

The foregoing discussion was confined to cable in duct with air as the intervening fluid. Its applicability to cable in gas-filled pipe at high pressures, where convection becomes the principal mechanism of heat transfer, requires further study.

The authors have done an excellent job in helping to establish the theoretical groundwork necessary to both encourage and guide experimental workers in the duct heating problem.

A. H. Kidder (Philadelphia Electric Company, Philadelphia, Pa.): This paper by Buller and Neher, together with two previous papers by Mr. Neher,[1,2] completes presentation of the steady-state considerations involved in a project which was started about four years ago when Philadelphia Electric Company interested Mr. Neher in undertaking an investigation of fundamental relationships, as necessary to determine approximately what pipe-type cable circuit load ratings would be accurately comparable with the load ratings of conventional cable circuits in ducts.

The thermal resistance through the spaces between the cable sheaths and the pipe or duct wall inclosures is an important link in the thermal circuit. It had been hoped that a general relationship could be developed in such a form that all of the differences be-

tween cables in air in ducts and cables in high-pressure gas or oil-filled pipes could be explained in terms of the physical constants which characterize the respective fluids and the pertinent geometrical relationships.

The method presented by Buller and Neher has approximately achieved this result, at least to the extent of permitting the correlation of data obtained by various investigators at various times in various constructions. It does not disturb me particularly to find that there is some apparent difference between the effects of Transite and fiber duct walls, respectively, under the conditions which prevailed at the time the tests were made. I think we should hesitate to attach much significance to these apparent differences because there was no attempt to control the moisture content in the fiber or the Transite, or even to make the tests under conditions comparable to those to be expected in the usual exposures to natural but variable moisture conditions to be encountered in underground structures. The significant point is that Buller and Neher have obtained a correlation which now permits estimating the thermal resistance from cable to pipe or duct wall with sufficient accuracy, so that little, if any, practical improvement in cable load ratings can be gained by introducing further refinements in their analysis of this part of the thermal circuit.

F. H. Buller and J. H. Neher: Mr. Norris and Mrs. Buckland have taken us somewhat to task for our apparent inconsistency in expressing our physical units in one system and our geometric units in another. For better or worse it has long been the custom in cable rating procedure to express the physical units involved in the watt-second-centimeter-gram system, and to express lengths in feet and diameters in inches. In developing our equations it would have been more consistent to have expressed the latter quantities also in centimeters, and then to have converted the final expressions to the system of measurement used in practice. We chose to use the mixed system throughout, however, in order that the reader might be able to use any equation in the development, directly, without encountering the uncertainty which inevitably arises as to whether you multiply or divide by the transformation constants.

The use of the term "surface resistivity factor" is a slightly different matter, and as our mentors have pointed out, it has dimensions which are not those of true, or volumetric, "resistivity." Here again, this nomenclature has been hallowed by time and is thoroughly understood by cable engineers, for whom this paper was written. It should be stressed, however, that this "surface resistivity" is not a fundamental physical quantity, in the sense that volumetric resistivity is; but as pointed out, is the resistance of a unit surface of a film which, purely for purposes of convenience, is assumed arbitrarily to represent the entire thermal resistance of the composite heat transfer effects operating in the region between cable sheath and duct wall. It is unfortunate that we do not have a more distinctive name for it.

Mr. Burrell has presented a thoughtful discussion of the assumptions which we have made in developing the theory used for correlating the test data. In this respect, a book by Prof. McAdams[1] gives a constant for the convection film on the outside of a cylindrical surface in a free medium which is about 20 per cent lower than that for the inside of a pipe and which we have used for both films. We have not distinguished between the two constants because no information is given as to the values of these constants when the cylinder is placed within the pipe. While a formula for the conduction component in a non-concentric system is given by Whitehead and Hutchings[2] it is far too complicated to use in this analysis, and it reduces substantially to the concentric formula which we have employed except for extremely small separations between the cylinders at one point. Further there is considerable experimental evidence to support the assumption that the emissivity constant is substantially unity for the types of cable surfaces employed.

Discrepancies were expected, because of the assumptions which had to be made, and because the physical location of the cables within the pipe cannot be controlled. We have used assumptions and theory only to obtain a sensible understanding of the problem with which we have to deal and to determine what simplifications can justifiably be made in order to obtain practical working expressions. These working expressions were then developed directly from actual tests rather than from theory. We do not share Mr. Burrell's desire for working expressions of sufficient complexity to identify the separate effects of the three modes of heat transfer.

Dr. Wiseman's simplified formulas for calculating h_{sd} (on a per cable basis) for three cables in an oil-filled pipe or in a gas-filled pipe at 200 pounds per square inch are very interesting and similar formulas may be derived from Figures 3 and 4 of the paper assuming that Q, P, and T_m have fixed typical values. Unfortunately Dr. Wiseman's derivation of the equivalent β in his formulas gives values which are not comparable to β as defined in this paper. The corresponding relationship for β as defined in the paper is

$$\frac{h_{sd}}{3} = \frac{0.00411\beta}{2.15D_s}$$

and this yields $\beta = 290$ for the oil-pressure system and $\beta = 450$ for the gas-pressure system.

We cannot accept his formula for the oil system since its corresponding value on a total heat flow basis is $H_{sd} = 1.15/D_s'$ which is equivalent to $Q/\Delta T = 3.9$ for $D_s' = 4.5$. None of the tests cited in Table III of the paper give any support for so high a value.

Dr. Wiseman also assumes that the overall thermal resistance varies inversely with the diameter whereas we believe that a more representative variation may be deduced from the slope of the curves of Figures 3 and 4 in the vicinity of the typical operating points. Thus for $Q = 25$ watts per foot and $T_m = 50$ degrees centigrade, we derive the simplified expressions

$$H_{sd}\ (\text{oil}) = 0.70/D_s^{0/2}\ \text{thermal ohm feet} \quad (1)$$

$$H_{sd}\ (\text{gas at 200 psi}) = 1.20/(D_s')^{0.7}\ \text{thermal ohm feet} \quad (2)$$

The corresponding equations on a per cable basis and with three cables in the pipe are

$$h_{sd} = \frac{1.44}{\sqrt{D_s}} \text{ and } h_{sd} = \frac{2.07}{(D_s)^{0.7}} \text{ respectively}$$

Figures 3 and 4 are intended to give practical working values of β or H_{sd} over a wide range of operating conditions. Mr. Greebler is right in pointing out that the effect of temperature variations upon the radiation component is considerably greater than the effect of variations in the convection term which is the essential variant in Figure 3. The inclusion of the temperature of the medium in the working expressions would vastly complicate them, however, and as a practical matter this is unnecessary.

In all of the Greebler-Barnett data[3] it will be observed that β varies inversely as $Q^{1/4}$ within the accuracy of measurement. The dependence of β upon D_s cannot be evaluated from this data since only a single value of D_s was employed, but since the convection term theoretically varies directly as $Q^{1/4}/D^{1/4}$ we believe that the temperature variation in the radiation term which Greebler has mentioned will be accounted for with sufficient accuracy by expressing the Greebler-Barnett data for fiber and Transite ducts in the form

$$\beta(\text{fiber}) = 1120D_s^{1/4}/Q^{1/4}\ \text{degrees centigrade square centimeters per watt} \quad (3)$$

$$\beta(\text{Transite}) = 990D_s^{1/4}/Q^{1/4}\ \text{degrees centigrade square centimeters per watt} \quad (4)$$

This will have the effect of changing the slope of the curves when plotted in accordance with Figure 3.[4]

The corresponding values of H_{sd} assuming a working value of $Q = 10$ watts per foot are

$$H_{sd}\ (\text{fiber}) = (2.59/D_s^{1/2}) + 0.33\ \text{thermal ohm feet} \quad (5)$$

$$H_{sd}\ (\text{Transite}) = 2.29/D_s^{1/2}\ \text{thermal ohm feet} \quad (6)$$

While further theoretical and experimental work may well be undertaken in order to clear up some of the apparent discrepancies between theory and practice and to yield more factual data on the performance of cables in duct; we agree with Mr. Kidder that little of any practical improvement in cable load ratings will result. We do not wish to discourage further efforts in this direction, but we feel that it is sufficient to base cable ratings on Figures 3 and 4 of the paper or more simply on equations (1, 2, 5, and 6) just given.

Development of Improved Luminous Sign Cable

L. F. ROEHMANN
MEMBER AIEE

E. W. GREENFIELD
MEMBER AIEE

TEN million feet of luminous sign cable were used last year, enough to be stretched along the entire Appalachian Trail (from Maine to Georgia). All of this cable is at high voltage, nominally rated at 5, 10, and predominantly, 15 kv. Nevertheless, installation techniques follow, by and large, accepted practice of low-voltage utilization wiring. Cables in outdoor installations are sometimes laid on roofs, in gutters, over cornices. They are exposed to sun and rain, dirt and salt deposits, notably near the sea coasts. Joints and terminals, integral components of power cables, are almost unknown to the luminous sign trade. Rubber and friction tape is applied for joints, and terminals are made by stripping the insulation. Furthermore, post-war business expanded not only in number of installations (nearly every roadside inn and many filling stations have neon signs) but equally important, the power rating of the individual installation was successively increased, first from 30 to 60, later from 60 to 120 milliamperes.

The Problem

This situation has been a challenge to the manufacturer of luminous sign cable. For various reasons there is little hope to elevate neon sign cable to the level of power cable and to ask for, and to expect, properly made joints and terminals. Rather, the problem presented to the designer is as follows:

1. Develop luminous sign cable which is safe in operation, unaffected by moisture, contamination, and salt deposits at the ends.
2. Design cable which requires no special knowledge and skill in handling but can be installed by any electrician familiar with utilization wiring.
3. Meet existing specifications,[1] notably for flame resistance.
4. Remain competitive.

To show how this challenge was met is the essence of this paper.

Previous Designs

Pre-war luminous sign cables were generally designed with a number 14 American Wire Gauge stranded copper conductor with rubber as insulation, and with saturated or lacquered textile braids as covering (sign cables have no shield). Comparatively large diameters provided the necessary dielectric strength, and flame-resistance was obtained by suitable impregnants. End failures due to contamination occurred on occasion, and necessitated replacements, notably in exposed locations.

During the last war, polyethylene was developed and used in ever-increasing quantities for the manufacture of high-frequency cables (type *RG-/U*). Its outstanding dielectric properties, coupled with the fact that the mills had acquired the "know-how" of its processing and extrusion, made it a natural choice for the insulation of post-war luminous sign cables. Unfortunately, plain polyethylene when ignited continues to burn and develops flaming drops. It is therefore unacceptable for luminous sign cable. As a consequence, the first post-war sign cables had an extruded plain polyethylene core over the conductor, and an over-all extruded, flame retardant, black polyvinyl-chloride jacket. Conservatively, the first cables of this type had a rather heavy wall of polyethylene (85 mils, for 15-kv cable). Soon afterwards, however, one manufacture reduced the polyethylene wall thickness to 55 mils, for 15-kv cable, and other manufacturers followed suit. Such *GTO-15* cable (Gas Tube and Oil-burner ignition cable, 15 kv) has an over-all diameter of approximately 1/4 inch, smaller than a pencil but operates satisfactorily, dielectrically, because of the high dielectric strength of polyethylene, and satisfactorily as to flame-resistance, because of the polyvinyl-chloride jacket. End failures due to contamination, however, and failures in splices continued to occur occasionally.

Laboratory Investigations

In fact, it were reports of certain end failures, notably in installations along the sea coasts, which accelerated our development program on this type of cable. As a first step, the operation of a complete installation with transformer, tubes, and cables was studied in the laboratory.

Operating Conditions—Electrical

Figure 1, top, shows schematically a luminous sign transformer: primary, 115 volts, 60 cycles; secondary, 15 kv, 60 milliamperes. This is a high-reactance transformer which inherently limits the current to the rated value.[2] The transformer is connected by means of *GTO* cables to a luminous sign (two sections, with the midpoint grounded). Figure 1, bottom, shows high-voltage rms; high-voltage, crest; and sign current as a function of primary voltage. Before the sign ignites, the voltage shape is approximately sinusoidal, and the ratio of crest to rms is approximately 1.4. Tube current is zero. Once the tube ignites, at some 60-volts primary, the transformer rms voltage value decreases but the crest reaches 10 to 12 kv to ground. Ratio between crest and rms then becomes 3.5, at rated primary voltage. The reason is evident from Figure 2 which shows oscillograms of the

Paper 50-53, recommended by the AIEE Insulated Conductors Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted October 3, 1949; made available for printing December 7, 1949.

L. F. Roehmann and E. W. Greenfield are both with the Anaconda Wire and Cable Company, Hastings-on-Hudson, N. Y.

Figure 1 (left). Neon sign load characteristics before and after tube ignition

Figure 3 (above). Simulated service tests for terminal tracking strength investigation

high voltage before and after ignition of the tube. After ignition, the gas column breaks down, every half wave of 60 cycles, and the steady state is reached after a damped oscillatory discharge. Oscillation frequency depends on the circuit parameters. In the case shown it is in the order of 4 kilocycles per second. Small wonder then that these high crest voltages, in conjunction with an elevated frequency, necessitate an insulation of exceptionally high dielectric strength.

Operating Conditions—Physical

But this is only half of the story. Outdoor signs, where most of the failures occurred, have the cables installed, or supposedly installed, in grounded metallic conduit. Between conduit end and high-voltage sign electrode, the National Electrical Code[3] specifies a clearance of four inches for the commonly used *GTO-15* cables. It is in this clearance length that trouble due to intense surface discharges developed on occasion, particularly in locations near the sea-coast.

Simulated Surface Discharge Tests on Cables

Early in the course of the laboratory investigation, salt deposits were suspected as a contributory factor for such terminal discharge failures. A set-up was constructed therefore to simulate field conditions and to induce terminal "tracking" failures in the laboratory. Figure 3 shows the apparatus. A neon sign transformer operating on a neon sign load is connected to the cables under test which are installed in grounded conduits. The conductor is connected to a terminal block, and the 4-inch exposed length is alternately sprayed with sea-water and fresh water, with wind-drying (compressed air) and calm-drying periods in between. The cycle as arbitrarily established is given in Table I.

Table I. Spraying Cycle

Sea-water spray	5 minutes
Wind-drying	25 minutes
Calm-drying	1½ hours
Fresh-water spray	5 minutes
Wind-drying	25 minutes
Calm-drying	1½ hours
Total time, one cycle	4 hours

Figure 2. Oscillograms of high voltage

(Left) before tube ignition
(Right) after tube ignition

The main idea of the test procedure was to have first, a salt deposit dried on, and afterwards washed off by a rain.

In testing cables with this equipment, ten spray cycles were tentatively established as a satisfactory limit. It was found that a good insulation or covering which stands ten spray cycles will stand many more while a poor dielectric will fail before 10 cycles are completed. Furthermore, ten spray cycles were established for practical reasons because they are completed in a 5-day week (two 4-hour cycles per day).

Slab Cell Tests

In addition, for evaluating the surface discharge strength of compounds, a slab cell was built in the course of our development work. Such a cell dispensed with the necessity to manufacture luminous sign cables for the sole purpose of compound evaluation. The cell, Figure 4. is fashioned after one described some years ago by K. S. Wyatt[4] which, in turn, appears to have been based on a Swiss design. Basically, two concentric electrodes are placed on the test material in slab form, and salt water, containing some wetting agent, is dropped on the slab into the space between the electrodes. Dropping rate is approximately one drop every three seconds, and the number of drops to surface breakdown is then an index of the surface discharge strength. As we were interested in compound evaluation for luminous sign cables we energize the cell from a neon sign transformer operating on a sign load. Such high-voltage opera-

Figure 4. Slab cell for evaluating tracking strength of insulating materials

tion necessitated a safety interlock. In addition, a sensitive counter is provided for counting the number of drops to breakdown. A specimen fails when the neon sign permanently extinguishes, after which the number of drops is read on the counter. Similar tests have been described recently by Yarsely and Grant.[8]

In making tests with the slab cell, no number of drops was specified, even tentatively, as a criterion for good and poor dielectrics. The slab tests were exploratory, and intended to give an idea of classes of dielectrics and surface treatments, rather than of specific formulations or colorings. It appears that dielectrics which fail at less than 50 or 60 drops will be unsatisfactory with respect to tracking, and not worth investigating further for sign cable application.

Point Discharge Tests

Another set-up was devised for testing "wet-ground contacts" that is, point discharges which may occur when a wet cable, otherwise ungrounded (for instance, mounted on glass pedestals) touches a grounded structure (gutter, metal frame of the sign, or the like). Such surface point discharges of an unshielded high-voltage cable may occur at any point (not at the ends). They were considered as a possible source of occasional failures for instance well inside a grounded conduit in contradistinction to end discharge failures, which are relatively more common.

The test set-up is shown in Figure 5. The cables, connected to a neon sign load and with ends well protected, are draped over a grounded metal angle and intermittently sprayed with artificial rain. The illustration, a double exposure, shows point discharges at the two cables in the rear.

Figure 5. Point discharge test

Notice discharge on the two rear cables where they make contact with grounded angle

Figure 6. One-year immersion test

Installation of cables and splices in water tank

Long-Time Water Immersion Tests

Finally, to study the performance of splices and unspliced straight lengths, 20-foot specimens were installed in a water tank as shown schematically in Figure 6. With the ends well protected so that end discharge effects were eliminated, the specimens were installed partly submersed, partly in air but under a pipe providing artificial rain. In a 1-year test, rain was provided daily during summer, and twice weekly during winter, to induce point discharges and to make up for the evaporation loss. The cables were connected to a 120-milliampere sign transformer operating on a neon sign load.

Results

The results of these tests are reported and discussed in somewhat different order than that given previously.

One-Year Immersion Test

All cables with rubber-and-friction-tape splices failed in the submersed splices. All continuous lengths with all-plastic insulation withstood the test regardless of construction and size. An exception was one specimen cut from an experimental, preproduction run. It failed under water. No failures due to point discharge occurred though point discharges (sparks) were observed at the grounded angle supports, after wetting.

We conclude therefore as follows:

1. Rubber-and-friction-tape splices are not permissible in exposed sign cables. Plastic tapes, for instance polyethylene tape, may show better performance but have some practical disadvantages: they are fairly expensive, and one cannot expect that the electrician who installs a sign will have such tape at hand and use it. As sign cable runs are short as a rule, and sign cable is fairly inexpensive, only continuous lengths should be used, particularly in exposed, outdoor installations.

2. All-plastic insulated cables are adequate even under severe operating conditions pro-

Figure 7. Luminous sign cable GTO–15, polyethylene insulation, polyvinyl-chloride jacket

Jacket damage due to point discharge

vided the question of end-discharge is taken care of (ends either immune to tracking, or ends properly prepared or protected).

3. Point-discharges while observable are too weak to cause, at most, more than superficial damage.

Point Discharge Tests

The point-discharge tests shown in Figure 5 confirm the last conclusion. Point discharges develop only when the cable surface is "mottled," that is, partly wet and partly dry. Neither complete wetting nor complete drying is able to produce them. Also, some surfaces and finishes (for instance, lacquered glass braid) are more conducive to point discharges than others. The surface voltage is high, as measured with probe ring and electrostatic voltmeter. The energy involved, however, is so minute that even repeated "mottling" produces, at worst, but superficial damage. Despite patient efforts, no breakdown from point discharge could be induced in the laboratory on any cable. The small damage obtained on a polyvinyl-chloride jacket is shown in Figure 7. As will be discussed later, polyvinyl-chloride is among the poorest materials regarding resistance to discharges when exposed to water spray.

We conclude therefore as follows:

1. Point discharges of unshielded high-voltage cable inside a wet conduit, or at a metal support, are not conjectures but an actuality.[4,7] They can be seen and photographed, and the voltage can be measured. However, in luminous sign installations the energy involved in these brush discharges is so minute that, under the worst possible conditions, not more than superficial damage will occur.

2. It seems unlikely that the rare failures inside a grounded conduit can be ascribed to point discharges only, without contributory factors such as insulation damage from a sharp edge or burr or foreign matter, overstressing in pulling, or the like.

Resistance to Surface End-Discharges—Simulated Spray Tests

The results of these tests are particularly important, as they furnish the basis for improved luminous sign cables.

First of all, the end failures obtained in the laboratory closely resembled those obtained in the field. Evidently, the test set-up reproduced the field conditions.

Secondly, all cables, regardless of size and specific construction, developed end failures in less than ten spray cycles. Representative cables tested are shown in Figure 8. Failures occurred on the commercially used rubber insulated cables. For instance, the all-rubber construction, without jacket or braid, failed in the third cycle. A rubber insulation, covered with an asphalt-saturated cotton braid showed particularly poor tracking re-

sistance: it failed in the first cycle. A cable with Neoprene jacket failed in the second spray cycle. A cable with rubber insulation and two lacquered glass braids failed in the second cycle. This cable, together with two other constructions, is shown in Figure 9.

Of particular interest are the polyethylene-core, polyvinyl-chloride jacket constructions which failed in the second and third cycles, Figures 8 and 9. When the polyvinyl-chloride jacket was cut back four inches and removed from the end, thus exposing the polyethylene insulation, no failure occurred within ten spray cycles. Clearly, it is the polyvinyl-chloride which has the low resistance to tracking and which is responsible for the poor performance under high voltage.* Contrariwise, polyethylene has a very high resistance to tracking. It is therefore recommended that for such cables the jacket be stripped off at least four inches back from the tube terminal.

However, such procedure is an expediency. It is not an ultimate solution because the cutting back, unless done with proper tools and with proper care, may damage the insulation, thus doing more harm than good. Furthermore, it seems illogical to provide a flameproof protection within a metallic conduit but to remove it where the cable emerges from the protective enclosure.

For these reasons, development work proceeded towards the following objectives:

Develop a plastic insulation for high-voltage application which has: high dielectric strength; flame resistance; and high tracking resistance.

Such compound to be extruded as a one-wall insulation, without protective jacket. Alternatively, develop a jacket which is flame resistant and tracking resistant, and which is to be extruded over an insulating polyethylene core.

Slab Tests

With these objectives in mind, a number of existing compounds, and new experimental compounds, were evaluated regarding their tracking resistance. Representative results are summarized in Table II. Corroborating the spray tests, polyethylene was again found to be excellent, and polyvinyl-chloride comparatively poor along with siliconed surfaces, neoprene and a number of other commonly used materials.

Experimental compounds were developed by our Plastics Laboratory in June 1948 which achieved the desired objective. These compounds were, essentially, mixtures of polyethylene and chlorine compounds. The latter constituent imparted flame-resistance to the former without lowering the dielectric and tracking strength of plain polyethylene to

* The following remark about polyvinyl-chloride insulations and jackets seems in order. Any impression gained from this paper that polyvinyl-chloride is generally unsuitable as insulation or jacket is erroneous. It is only for high-voltage application where the question of tracking resistance under moist conditions is important that polyvinyl-chloride has its limitation. In this connection, Boyer and Woodland[9] ascribe the relatively low tracking resistance of polyvinyl-chloride and similar compounds to their conjugated double bond structure. *HCl* is produced as one of the by-products of the discharge, and the carbon atoms link up rapidly.

For utilization wiring that is, at voltages in the order of 1 per cent of those discussed in this study, polyvinyl-chloride has its outstanding merits. Building wire with polyvinyl-chloride insulation is rightfully used in ever-increasing amounts. There is no better insulation for machine tool wiring than polyvinyl-chloride. Multiconductor control cables have polyvinyl-chloride insulation and a polyvinyl-chloride jacket. Communication cables for carrier current operation have a polyvinyl-chloride jacket over polyethylene-insulated conductors. It is only in the field of higher voltages where surface tracking becomes a problem that polyvinyl-chloride jackets are objectionable. The new flame retardant polyethylene-base compounds, fortunately, take over where polyvinyl-chloride is no longer adequate.

such a degree that the material would not pass the specified tests. Experimental lengths of sign cable were manufactured with such compounds both as 1-wall insulation, and as jacket over plain polyethylene. In every case, ten spray cycles were sustained without failure, and without any visible damage to the ends.

Commercial Compounds

At this stage of development, one of the large chemical manufacturers offered us new, experimental, flame-retardant polyethylene-derived compounds for evaluation. This offer fitted accurately into our development program. All the routine physical and dielectric tests were undertaken. One compound, which we have tentatively designated as type *FR* (flame retardant) was selected. Some of its physical and dielectric properties are given in Tables III and IV. Significant physically are the extremely low cold bend limit on one end of the temperature scale, and the high softening temperature (over 100 degrees centigrade) on the other. Dielectrically, the compound has a very low power factor, comparable to oil-impregnated paper, and a dielectric constant of about half of that of rubber. The consequences are low dielectric loss at high voltage, and reduced capacity per unit length. The latter factor may have some future bearing on *Section 6031g* of the National Electrical Code which now limits cable runs of cable above 5 kv to ground to 20 feet, in metal raceways.

Experimental sign cables were manufactured from the new compound. Some of them had the type *FR* compound extruded in one wall (without a jacket), others had it extruded as a jacket over a core of plain polyethylene. These cables were subjected to the routine sign cable tests (mandrel test, flame-resistance test). In addition, they were subjected to the special tests described in this paper (spray test for tracking resistance, point discharge test, and long-time immersion test) and to the tests reported in Tables V, VI, and VII, namely dielectric properties as a function of voltage and of time. The test results indicated that the new cables met not only the requirements previously set up for this type of service, but also were highly tracking resistant. Both types of cable construction have been tested and approved by the Underwriters' Laboratories.

These cables maintain flexibility at very low temperatures, are resistant to heat, to moisture, and to the many solvents to which polyethylene can be exposed. Most important, they have the following features:

1. They are safe in operation—they withstand the ultra-conservative mandrel test for dielectric strength.

2. They are flame-retardant—they do not support combustion and develop no flaming drops.

3. They are the only sign cables with high tracking resistance—they will not develop end failures in moist and dirty locations. There is no need for special end preparation.

Discussion

G. S. Eager, Jr. (General Cable Corporation, Bayonne, N. J.): The authors have presented a great deal of useful information concerning the postwar *GTO-15* cables. Since these cables operate at a relatively high voltage and the terminals are generally not protected, surface tracking may develop under some conditions.

The authors have chosen to represent the conditions which cause surface deterioration by a special cycle of fresh- and salt-water spray, with intermediate drying periods. While this has contributed to their study, we believe that more realistic information can be obtained by the aid of a quite different cycle of testing. During the four-hour-long cycle, significant deterioration occurs during only a very small proportion of the time. No account is taken of the serious effect of soot deposits and of the fact that the deteriorating effect of a mist or fog is much longer lasting than that of a rain which soon washes away contaminants which have been accumulating in dry weather. Moreover, in our interior cities, the deteriorating conditions usually do not include salt spray.

In our accelerated tests, intended to simulate the damaging kinds of service conditions, we have represented these by soot accumulations which may be accompanied by an atomized spray of fresh water or of salt water. Our tests show that, under dry conditions and with natural soot contamination only, satisfactory life can be expected from cables made with (1) polyethylene core, polyvinyl-chloride jacket, (2) rubber core, glass braid, lacquer, (3) one wall of polyvinyl-chloride. These results are substantiated for the most part by field performance.

If, now, these soot-covered dry samples are sprayed with tap water by means of an atomizer, our tests show that a polyethylene surface is superior to a polyvinyl-chloride surface in resisting surface tracking. These simulate conditions inland from our coasts where soot or dust and rainwater are the contaminating agents.

Along the Atlantic and Pacific coasts, salt must be added to the soot and water in order to make a reasonably complete contaminant test. Such tests show that while natural and flame-resistant polyethylene can be made to fail by the formation of a semiconducting path on the surface with normal voltage and creepage distances, the two types appear to be not greatly different in ability to resist the formation of a semiconducting path on the surface with soot and salt-water contamination.

The fact that natural polyethylene with a suitable creepage distance is giving good field service indicates that field conditions

are generally less severe than the surface contamination conditions of our soot-salt-water tests.

S. J. Rosch (Anaconda Wire and Cable Company, Hastings-on-Hudson, N.Y.): The paper by Dr. Roehmann and Dr. Greenfield is a real contribution to a phase of electrical engineering, replete with a number of phenomena on which very little information has been available in the engineering literature.

During the past fifteen years, the present discusser has had the opportunity of personally examining numerous luminous-sign installations where failure of the high-voltage conductor had occurred. The defects examined were not confined to any one design but included every type available on the market. Many of these defects were of a type that readily disclosed the cause, particularly those which occurred due to flashover from the protruding end of the cable to the metallic conduit in which it was installed. However, there were numerous other instances where no defects appeared at the protruding ends but rather in that portion of the length included well within the conduit. These latter defects occasionally were accompanied by very visible signs of tracking along the surface of the outer covering; evidence of such tracking sometimes even was visible below the fibrous outer covering where some type of rubber compound was used as insulation.

The experimental laboratory investigations described in the paper very ably reproduced many of the different types of defects found to have occurred under actual service conditions, thereby throwing considerable light on the mechanism leading to these failures. Once these mechanisms were understood the way was opened to eliminate them, and this present paper offers one method for such approach, which has proven very effective. Others will undoubtedly be developed as soon as these failure mechanisms are thoroughly understood.

The implifications in this paper should go far beyond the question of improved luminous-sign cable. The solution for the development of the latter consisted in finding a thermoplastic material possessing excellent flame-retarding properties without dripping when exposed to flame, excellent resistance to a wide variety of liquid media, resistance to weathering and ozone, and, at the same time, possessing electrical properties comparable to some of the very best electrical insulating materials available to the industry to date. When it is further considered that this new material can be flexed during installations at subzero temperatures, that it readily can be applied with existing facilities, and that, coincident with these properties, it also possesses excellent resistance to high-voltage surface discharges, it becomes apparent to the cable designer and user that here is a material which offers a new approach to the solution of a number of vexing cable problems in the power, communication, and signalling fields.

L. F. Roehmann and **E. W. Greenfield:** Mr. Eager's discussion is much appreciated. There appears to be general agreement with regards to the superiority of polyethylene and polyethylene-derived materials in resisting surface discharges induced by electrolytic contaminations.

There are a few points to be clarified, however. Mr. Eager questions the severity of our aging cycle and indicates that an atomized spray is more severe than a watery downpour. We agree. In all of our tests, a finely divided spray has been used; this is evident from the paper. It is significant to note that only two or three spray cycles are sufficient in most cases to eliminate all but the best track-resistant materials.

With regard to the question of salt spray versus soot contaminations, we believe there may be some misunderstanding concerning the basic phenomena involved in tracking. Tracking is a surface discharge along an insulator in the presence of moisture and an electrolyte. A dry surface, even if contaminated with, for instance, soot, does not track; neither does a moist surface when an electrolyte is absent. On this basis, even soot plus water does not necessarily induce tracking because soot, in its narrow sense, is finely divided carbon. The soot particles are islands, conductive islands so to speak in a sea, but unless the sea is electrolyzed, either because the soot or the water is impure, no tracking will take place. On the other hand, sea water, with its known and reproducible composition, is a strong electrolyte, and readily induces tracking.

Use of a sea-water spray was predicated primarily because most of the field tracking failures came from the Eastern and Western seaboards. However, it was soon realized that the principle by which any dirt or other surface contamination induced tracking was by virtue of the ionizable salts present in the contaminants. Thus sulphates, carbonates, phosphates, and many others, both inorganic and organic, when present as inherent ingredients of surface contaminations, liberate free ions in the presence of moisture and initiate the surface discharges which prove so destructive to most cable materials. The dry dust itself is unimportant—the hydrolysis of the salts is of greatest importance. It is for these reasons that standard sea-water spray was adopted as contaminant; we believe it has answered the purpose admirably.

It gives us satisfaction that the tests made at General Cable Corporation confirm our findings of the superiority of polyethylene over polyvinyl-chloride regarding tracking. On the other hand, Mr. Eager states that "the two types appear to be not greatly different in ability to resist the formation of a semiconducting path on the surface with soot and salt-water contamination." This brings us back to the picture of the carbon islands in an electrolyzed sea. If the islands become so numerous, or so large as to form a semiconducting parallel path to the cable termination, the cable end may well be damaged by the heat generated in this parallel path. This, however, is not tracking. And while this differentiation may sound academic, it should be emphasized that no failures were reported to us on plain or flame-retardant polyethylene terminations.

Thus, it seems to be tracking one has to contend with in the field, and the new nontracking flame-retardant polyethylene-derived resin seems to be a distinct progress in the art.

The authors are appreciative of Mr. Rosch's kind words. As he has stated, the findings of our present paper are applicable to many other types of cable services. We hope to bring, in due time, such further developments to the attention of the engineering profession.

Heat Transfer Study on Power Cable Ducts and Duct Assemblies

PAUL GREEBLER
NONMEMBER AIEE

GUY F. BARNETT
ASSOCIATE AIEE

STUDIES of heat transfer on power cable in duct have indicated the need for more experimental data to establish thermal resistivity values for several components of the duct system, particularly that portion of the heat flow path from the cable sheath to the outer duct wall surface. Theoretical considerations of heat transfer from the cable to the outer duct wall surface have treated the duct wall as an isothermal surface; and, generally, no consideration has been given to the effect of the thermal resistivity of the duct material upon the heat flow from the cable. These approximations are made necessary in theoretical studies of cable systems by the complex geometry of the duct assembly, the cable sheath resting nonuniformly at the bottom of the duct. While such studies, supported by the experimental evidence available, yield reasonably accurate thermal resistivity values, the effects of a nonisothermal duct wall and of the thermal resistivity of the duct material can be taken into account by performing measurements on a duct assembly.

In 1938 a study of heat flow in duct systems was begun at the Johns-Manville Research Center to determine the thermal resistance of the components of the heat flow path in a duct assembly. Transite and fiber duct, the latter possessing the higher thermal resistance, were selected for the tests.* Preliminary experiments were performed with each type of duct encased in concrete and buried in earth, an iron pipe enclosing a heater resting on the bottom of each duct. The temperature of the iron pipe in the Transite was sufficiently different from that in the fiber duct, both measured under conditions of equal heater load, to justify further study of the effects of the thermal resistivity of the duct upon the thermal resistance from sheath to outer duct wall surface in a cable system.

After about two years, during which time tests and procedures were established, the control apparatus was designed and assembled; and work was started on the first stage of the 2-stage program, which was planned to include investigation of (1) ducts in air; (2) single duct encased in concrete. This paper contains a description of the tests covering this program, and the application of the test results is indicated to the solution of heat flow problems in duct banks.

Thermocouple Assembly

Eight-foot lengths of Transite and fiber duct were employed for the tests in air. The main components for this test are the duct, the lead sheath resting on the bottom of the duct and containing a Calrod heater along its axis, and the apparatus for regulating the power supply and measuring the thermocouple electromotive forces.

Since the geometry of the duct assembly is not radially symmetric, it was realized early in the study of this problem that, in order to obtain an accurate average temperature around a duct surface, it would be necessary to use a large number of thermocouples spaced circumferentially around the surface. Furthermore, it was recognized that the temperature distribution along the length of the duct would be nonuniform due to the irregular contact between the inner duct wall surface and the lead sheath; and so it was necessary to space the thermocouples along the duct length as well. A 2-foot length of duct, placed in the center of the 8-foot assembly, was employed for the measurements. Thus 3-foot sections of duct on each side of this test length served as guards, reducing end effects and thereby allowing the test area to more closely represent a small section of a long duct.

A preliminary survey of the temperature distribution around the duct surfaces showed that 48 thermocouples along the 2-foot length placed in a 3-turn helix of 16 couples per turn would provide enough temperature readings to yield a true

Paper 50-55, recommended by the AIEE Insulated Conductors Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted July 18, 1949; made available for printing December 8, 1949.

average surface temperature. Figure 1 shows the assembly of the temperature measuring thermocouples on a test length of fiber duct. The constantan wires are soldered to a narrow strip of thin copper foil, which is cemented to the outside surface of the duct. An identical thermocouple assembly is employed on the inside surface. As can be seen in Figure 1, the constantan wires on the outside surface helix are run about two inches along the surface and then inserted into holes taking them inside the duct.

All of the constantan leads were carried inside the duct to reduce the possibility of abrasion when set in concrete. Also, the leads were run along the duct surface for at least two inches to avoid change in the junction temperature by conduction along the wire. In order to permit the measurement of the average surface temperature of a duct by connecting the couples on that surface in parallel, the constantan leads were all cut to lengths of equal resistance. Consideration was given to the effect the mass of wires inside the duct might have on the surface temperature of the lead sheath and of the inner duct surface. Since the total cross-sectional area of the 96, number 30 Brown and Sharpe gauge constantan wires is equal to that of a single 10-gauge wire, it was concluded that this quantity of wire has negligible effect upon the heat flow.

The Transite and fiber ducts employed in the tests each had a 4-inch inside diameter and 0.31-inch wall thickness.

The Heating Unit

The lead sheath used in the duct assembly was cut from a lead pipe of $3^1/_2$-inch outside diameter and 1/8-inch wall thickness. The pipe was stored in the laboratory for over a year before the tests were begun, and so the lead surface had sufficient time to attain a high emissivity oxide coating. A 7.75-foot length Calrod heater, consisting of a coaxial nichrome wire and metallic shield separated by a refractory material, was placed along the axis of the lead sheath and held in place by thin Transite disk spacers. The shield was used as the return current lead to eliminate the possibility of inducing potentials in the thermocouple leads. The resistance of the Calrod heater was measured as approximately 3.4 ohms per foot with ten watts per foot heat flow in the assembled duct.

After some investigation, sand was found to be a suitable medium with which to surround the Calrod heater inside the lead sheath. Five copper-con-

stantan thermocouples made from number 24 Brown and Sharpe gauge wire were placed in a helical arrangement along a 2-foot length in the middle of the lead pipe. The duct assembly was then completed by placing the sheath inside the duct, the lead pipe resting on the bottom and forming an air crescent with the inner wall surface.

Apparatus

Figures 2 and 3 show the front and rear respectively of the control board. The power circuit controls and the thermocouple circuit instruments are numbered to simplify their identification.

The lead sheath temperature was maintained constant during a test run by means of the Celectray temperatue controller, which surveyed the control couples of each duct assembly once a minute. The control couples were mounted on the lead sheath, and the controller functioned to reduce the current through the Calrod heater when the lead sheath temperature exceeded the set value and to increase it when the temperature fell below the setting. Pilot lights on the control board showed which duct assembly was being surveyed by the controller at any given time. Although the controller has a sensitivity of 0.1 degree centigrade, the temperature variations of the sheath exceeded this quantity because of the appreciable thermal capacity of the duct system. The deviation from the set value was held, however, within 1 per cent of the sheath temperature setting, varying periodically between high and low values.

Energy dissipation in a duct heater during a test interval was measured with integrating wattmeters, and the average power was computed from the time interval of the test run. Thermocouple electromotive forces were measured with a type *K-2* Leeds and Northrup potentiometer, and thermocouple switches were connected so that the electromotive forces of each couple could be measured separately or an average surface temperature reading be made by connecting in parallel the couples on that surface.

Method of Test

All temperature measurements were made under steady-state conditions of heat flow. Thermal equilibrium was generally attained about 72 hours after the initial setting of the controller and power transtats, minor power adjustments being made during the first 48 hours of this period. This steady-state condition was maintained throughout the test period of three to six hours by controlling the temperature of the lead sheath and that of ambient air.

The ends of the duct were packed with rock wool to cut down convection, contributing to the effectiveness of the guard sections in eliminating end effects. Temperature measurements along the test length of the lead sheath during the test period showed variations from the mean temperature of about one per cent. These temperature variations were random along the test length of the sheath, with no indication of a maximum temperature near the center, indicating that the guard sections were effective in eliminating end effects. Along the top of the duct, the temperature was nearly constant along the 2-foot test length. Appreciable temperature differences were measured along the length on the bottom of the duct, but these differences were random and can be attributed to the nonuniform contact between lead sheath and duct wall.

Three "points" each at four different sheath temperatures were obtained for each duct, Transite and fiber, after thermal equilibrium had been obtained. A point consisted of obtaining a record, by means of the integrating wattmeter, of the power dissipated in each duct throughout the test period, recording the surface temperatures of the sheath and duct wall at intervals during the test period, and noting the ambient air temperature. The tests were run in a constant temperature room (34 degrees centigrade) so that little change was noted in the ambient air temperature.

Test Assembly

The assembled ducts were suspended side by side in air, with a separation of one foot, behind the control board. Temperature measurements in the air space between the Transite and fiber ducts showed that their mutual heating effects were negligible. Thermocouple leads were carried through the inside of each duct and connected to the terminal board.

The second stage of the investigation, namely the study of single duct encased in a concrete envelope, was carried out employing the following concrete mix: 440 pounds cement; 1,295 pounds sand; and 2,100 pounds 3/4-inch stone.

This is approximately a 1:3:5 mix, based upon the following densities: sand 100 pounds per cubic foot, stone 100 pounds per cubic foot, and cement 94 pounds per cubic foot. No allowance was made for moisture content of the sand.

The concrete casings were aged before tests were started until the electrical resistance of wood blocks containing metal electrodes, which were cast in the concrete, reached an equilibrium condition. The aging period, as judged by this method, was approximately four months.

Seven thermocouples were placed around the surface of the concrete envelopes to obtain surface temperatures. With the additional observation of outside concrete surface temperature, the test method was identical with that described for ducts in air.

Figure 4 shows the concrete encased ducts in test position behind the panel board. The concrete envelopes are spaced ten inches apart, and the temperature in the air space midway between the encased ducts exceeded room temperature by less than 1 degree centigrade. A duct bank of experimental conduit is shown in addition to the Transite and fiber duct assemblies. Figure 5 shows a cross-section detail of ducts in concrete.

A second series of tests was conducted on Transite and fiber duct, using two additional samples, to add weight to the original data obtained. The test assembly in air was identical with that described before except that the length of the duct assembly was reduced to six feet and the number of lead sheath thermocouples was increased to seven. An additional change made for the tests on ducts in concrete was to increase the size of the concrete envelope so that the total cross-section of the duct bank was a 12-inch square. It is believed that this larger concrete envelope more closely represents a single-duct bank buried underground. The method of test employed in the second test series was identical with that of the first series except that "points" were taken at a larger number of lead sheath temperatures with only one "point" for each temperature. Also the tests were run in a lower ambient room temperature (about 26 degrees centigrade). Data pertaining to the first and second series of tests will be designated respectively as Series 1 and Series 2.

Results

Table I contains typical observations and calculations from the tests on ducts in air and in concrete. Although this table contains only a small number of the total test points employed in the investigation, it shows the method of calculation used to obtain the values of thermal resistance and resistivity employed in the illustrations.

Values of thermal resistance are plotted

* Number in parentheses represents the test series from which the data was taken.

** β, β_d, and β_c are surface resistivity factors respectively from sheath to duct wall, from duct wall to ambient air, and from concrete to ambient air. ρ_d and ρ_c are volume resistivities of duct and concrete respectively. These thermal resistivity values are computed from the following equations

$$\beta = \frac{R_{ths} D_s}{0.00411}, \quad \beta_d = \frac{R_{thd}' D_d}{0.00411}, \quad \beta_c = \frac{R_{ths}' D_s}{0.00411}, \quad \rho_d = \frac{R_{thd}}{0.012 \log_{10} D_d/D_i}, \quad \rho_c = \frac{R_{ths}}{0.012 \log_{10} D_e/D_d}$$

where R_{ths}, R_{thd}, R_{ths}', R_{thd}', and R_{the} are the respective thermal resistance values shown above from sheath to duct wall, duct wall to air, concrete to air, of the duct wall, and the concrete envelope; and D_s, D_i, D_d, and D_e are in inches the respective diameters of sheath, inner duct wall surface, outer duct wall surface, and equivalent concrete diameter.

against lead sheath temperature for the components of the heat flow path in the ducts, Figures 6 through 9. Figures 6 and 7 show the variation with sheath temperature of the thermal resistance from sheath to inside duct wall for ducts in air and ducts in concrete respectively. Since radiation through the air crescent between sheath and inside duct surface is an important factor in the heat transfer between these surfaces, the thermal resistance values decrease with increasing lead sheath temperature. It was not expected that the heat transfer due to convection would increase so rapidly with increasing sheath temperature as that due to radiation, the former varying nearly linearly with the temperature difference of the two surfaces, the latter with the difference in the fourth powers of the surface temperatures.[1]

Two general conclusions can be drawn from these curves regarding the relative thermal resistance values from the lead sheath to the inside duct surface. For a given sheath temperature, the thermal resistance is consistently higher for ducts in air than in concrete. Also the fiber duct consistently gives a higher resistance from sheath to inside duct wall than does the Transite duct. The influence of the concrete casing can be attributed to its effectiveness in producing more uniformity of the heat flow lines in the entire duct assembly, since its thermal resistivity is relatively low. Differences between the fiber and Transite assemblies can be attributed to the heat transfer from sheath to duct by direct conduction. The lead sheath "snakes" throughout the bottom of the duct, making a nonuniform contact with it. The duct material of lower thermal resistivity more readily conducts heat away from the lead sheath.

The difference in the thermal resistance from lead sheath to inside duct wall as between the Transite and fiber ducts is considerably greater in Series 1 tests than in Series 2. The deviation in the two test values for the fiber duct assembly is about 15 per cent of the resistance from sheath to duct wall, and we attribute it to the variable factor of contact area between lead sheath and the duct containing

Figure 10 (left). Temperature distribution around the fiber duct surfaces at 82 degrees centigrade lead sheath temperature. The solid lines represent the duct encased in concrete, the dotted lines in air

Figure 11 (left). Temperature distribution around the Transite duct surfaces at 82 degrees centigrade lead sheath temperature. The solid lines represent the duct encased in concrete, the dotted lines in air

it. This deviation is not unreasonably high, since considerations of the heat transfer from sheath to duct by Whitehead and Hutchings[3] indicate that variations in spacing between the sheath and the bottom of the duct produce considerable effect upon the thermal resistance of this component of the heat flow path.

Figures 8 and 9 show the thermal resistance of the duct itself as a function of lead sheath temperature for ducts in air and ducts in concrete respectively. This factor is small compared with the total resistance of the heat flow path from the sheath to ambient surroundings, but it serves to measure the effect of the thermal resistance of the duct upon the over-all heat flow through the duct assembly. The Transite duct possesses a lower resistance in concrete than in air, possibly due to the reduction in its outside surface resistance when in contact with the concrete envelope, Transite and concrete both being cement products. An anomalous curve in the set shown in Figures 8 and 9 is that for the Series 1 tests on fiber duct in air. Moisture content, among other factors, was considered as an explanation for this anomaly, but it was discounted since the Transite and fiber ducts were exposed to identical environments before and during the tests. Since the fiber duct samples employed in the two tests were identically assembled, no satisfactory explanation for the anomalous curve has been found.

The thermal circuit for ducts in air is completed with the outside duct wall surface resistance, typical values for which are shown in Table I. These values give the order of magnitude of the outside surface resistance of the duct wall, and in an actual installation, the exact value of this resistance will depend upon the temperature of the ambient surroundings as well as that of the outside duct surface. The resistance of the concrete envelope completes the thermal circuit for ducts in concrete in the laboratory installation, although the thermal resistance of the surrounding earth would also be considered in an underground duct bank. Table I also contains the thermal resistance values for the concrete envelopes, the values for the Series 2 tests being greater since the larger concrete envelope was employed for these tests.

Figures 10 and 11 are polar graphs showing the temperature distribution around the duct walls respectively for fiber and Transite ducts at a sheath temperature of 82 degrees centigrade. The solid lines represent ducts in concrete, dotted lines, ducts in air. The average temperature of the three thermocouples at each 22.5 degree radial position (corresponding to each turn of the three-turn helix of couples) was employed to obtain the points for these curves. The departure from uniform radial heat flow in the duct is shown by the large temperature difference between the top and bottom of the duct wall. Also since the lead sheath does not rest uniformly on the bottom of the duct, the heat flow is not entirely symmetrical about the vertical axis. The temperature distribution around the duct walls for ducts in air at the same sheath temperature is similar to that in concrete, except that a higher percentage of the total heat flow occurs near the bottom.

Figures 12 and 13 show reduced scale drawings of the fiber and Transite ducts with their lead sheaths. The temperatures on the duct walls at each 30 degree radial position were taken from the solid line polar graphs, Figures 10 and 11, representing ducts encased in concrete, and recorded on the drawings. The temperature falls off rapidly on the bottom half of the duct from the region of contact with the lead sheath, and it remains nearly constant on the top half. The direction of the temperature gradient through the duct is indicated by the arrows.

Calculations of thermal resistance for the heat flow components of a duct system are usually based upon accepted values of thermal surface or volume resistivity. Resistivity values are more useful to the cable engineer than are resistance values since the former are independent of the dimensions of the components of the duct system. The thermal resistance values obtained from the tests have been employed to calculate surface resistivity of the lead sheath, volume resistivity of the duct material and of the concrete, and surface resistivity of the outer duct wall in air. These values are shown in Table I, and since there is some interest in the surface resistivity of the outside of the concrete casing in air, these latter values are also given. Lead sheath surface resistivity values in fiber and

Table II. Thermal Resistivity Factors—10 Watts Per Foot Heat Flow

Thermal Component	Symbol	Resistivity
Lead sheath in fiber duct, surface resistivity	β	1,200 C cm²/watt
Lead sheath in Transite duct, surface resistivity	β	1,020 C cm²/watt
Duct in air, surface resistivity	β_d	1,110 C cm²/watt
Concrete in air, surface resistivity	β_c	1,120 C cm²/watt
Fiber duct, volume resistivity	ρ_d	480 C cm/watt
Transite duct, volume resistivity	ρ_d	200 C cm/watt
Concrete, volume resistivity	ρ_c	84 C cm/watt

Transite ducts are computed, as is customary in cable calculations, by formulating the thermal resistance from sheath to inner duct wall in terms of the sheath surface resistivity. The surface resistivity of the concrete envelope in air, and also its volume resistivity, is calculated by employing a diameter of a circle whose perimeter is equal to that of the square concrete casing. The concrete surface resistivity values are computed from the least precise of all the temperature measurements made on the duct assemblies, and the data should be weighted accordingly.

Figure 14 shows thermal surface resistivity values for various duct assembly components versus heat flow in watts per foot of duct. Curves of lead sheath surface resistivity in fiber and Transite duct are based upon average values from the four sets of tests; that is, Series 1 and 2 for ducts in air and in concrete. The curves of outside surface resistivity of the duct wall and the concrete envelope are each based upon average values from four sets of tests on both Transite and fiber. For a given value of sheath temperature, the outer duct wall surface resistivity is lower for Transite than for fiber since greater heat flow occurs in the assembly of the former, giving its outer duct wall surface a higher temperature. However, since resistivity values in Figure 14 are plotted against heat flow in watts per foot of duct, the outside duct wall surface resistivities for Transite and fiber duct in air are nearly equal and are represented by a single curve. It is interesting to note that the surface resistivity values of the various components are of the same order of magnitude. The curves in Figure 14 are extrapolated to a heat flow of ten watts per foot, and the values thus obtained may be used conveniently as duct constants in cable calculations. These values, along with the volume resistivities of duct wall and concrete obtained from the tests, are contained in Table II.

The temperature rise of a cable in a duct in air is given by the equation

$$T_c = \left(R_{\beta d} + 0.00411\frac{\beta}{D_s} + 0.012\rho_d \times \log_{10}\frac{D_d}{D_i} + 0.00411\frac{\beta_d}{D_d}\right)Q$$

where the four terms in parentheses represent the thermal resistances respectively from copper to lead, lead sheath to inside duct wall, across the duct wall, and outer duct wall to ambient air; and Q is the heat flow in watts per foot of cable. The symbols employed in the last three terms in the parentheses are defined in Table I, and the resistivity values are contained in Table II. The equation assumes that the sheath to duct resistance is independent of the duct diameter; and since theoretical considerations show that the sheath diameter is the primary variable in the heat transfer from sheath to duct, this assumption probably does not introduce an appreciable error in cable calculations. In temperature measurements on a cable sheath and the inside of an enclosing fiber duct encased in concrete, Barenscher[3] obtained data indicating the correctness of the inverse relationship between sheath diameter and thermal resistance from sheath to duct wall. The temperature rise of a given cable in a buried duct bank above ambient earth is obtained by replacing the fourth term in the equation with the expression derived by Neher[4], the latter taking into consideration the thermal resistance of concrete and surrounding earth and the heating produced by the other loaded cables in the duct bank.

Further tests on various duct materials should be of great value to cable engineers in establishing duct constants for these materials, and should add weight to the data submitted here on Transite and fiber duct. A more complete investigation is needed of the thermal resistance of the heat flow path from the cable sheath to the outside of the duct wall, including experimental data on the effect of variations in lead sheath and duct diameters and in thermal resistivity of the duct wall material. Tests on groups of ducts in a duct bank would also be of considerable interest, although the heat flow path outside the duct wall can be treated, with

Figure 14. Thermal surface resistivity versus heat flow for lead sheath in Transite duct, lead sheath in fiber duct, outer duct surface in air, and outer concrete surface in air

considerable degree of accuracy, with conventional methods of heat flow calculations.

Discussion

V. V. Mason (The Hydro-Electric Power Commission of Ontario, Toronto, Ontario, Canada): This discussion deals with two points which may not bear greatly on the practical value of the results attained by Mr. Greebler and Mr. Barnett but which are of some importance as regards the experimental method and the presentation of the results.

Presentation of Results

The authors present their results for the sheath-to-duct thermal resistance, R_{1h_2}, as a graph with the sheath temperature as the independent variable, and express some concern over the lack of agreement of these curves for the Series I and Series II tests. To find a more suitable quantity against which to plot R_{1h_2} consider that the rate at which heat is transferred from sheath to duct, being partly by conduction, partly by convection, and partly by radiation, may be written thus

$$P = k_1 \Delta T + k_2 (\Delta T)^{1.25} + k_3 \Delta (T^4) \qquad (1)$$

where k_1, k_2, k_3 are constants, and T is the absolute temperature in degrees Kelvin. The exponent of the temperature difference for the convection term actually may vary from 1 to 1.5, but 1.25 is probably fairly near the true value.

The thermal resistance R_{1h_2}, then, is given by

$$\frac{1}{R_{1h_2}} = \frac{P}{\Delta T} = k_1 + k_2 (\Delta T)^{0.25} + k_3 (T_s + T_w) \times (T_s^2 + T_w^2) \qquad (2)$$

where T_s and T_w are the temperatures in degrees Kelvin of the sheath and duct wall respectively, so that $\Delta T = T_s - T_w$ and $\Delta(T^4) = (T_s - T_w)(T_s + T_w)(T_s^2 + T_w^2)$.

We see then that R_{1h_2} is a function of

$$(\Delta T)^{0.25} + k(T_s + T_w)(T_s^2 + T_w^2)$$

where $k = k_3/k_2$.

In plotting their values for R_{1h_2} against sheath temperature, the authors have assumed that the duct wall temperature T_w is constant and that the convection term is negligibly small. To see how these quantities affect the appearance of the curves, Figures 1 to 4 of the discussion have been prepared from the complete test records which Mr. Greebler very kindly made available for this purpose. R_{1h_2} is plotted against $(\Delta T)^{0.25}$ in Figures 1 and 3 and against $(T_s + T_w)(T_s^2 + T_w^2)$ in Figures 2 and 4. Figures 1 and 2 are for fiber while Figures 3 and 4 are for Transite. Curves for duct in air and in concrete are given in each illustration because, for the purpose of this discussion, it is of most interest to compare all the values for a given kind of duct. Figures 1 and 3, R_{1h_2} versus $(\Delta T)^{0.25}$, would hold if the heat transfer due to radiation were small compared to that by convection, while Figures 2 and 4 would hold for negligible convection. That is, these figures represent extremes; any practical case will be some combination of the two, obtained by assigning a suitable value to k.

Examination of these figures indicates that for fiber ducts, the agreement between Series I and II in both air and concrete is considerably better when plotted against $(\Delta T)^{0.25}$ than when plotted against T_s or $(T_s + T_w)(T_s^2 + T_w^2)$. Transite, on the other hand, exhibits the most reasonable behaviour when $(T_s + T_w)(T_s^2 + T_w^2)$ is used for the abscissa. This would seem to indicate that with the fiber duct a large part of the heat transfer is due to convection, while with Transite, radiation is the more important mechanism. This difference may be ascribed to the difference in the thermal emissivities of the Transite and fiber surfaces.

The agreement between the two series of runs is still far from perfect, but does appear to be considerably improved. Another possible point of difference between the various tests not considered by the authors is the presence of the thermocouple leads with regard to their effect on the convection currents. Small changes in their position could affect materially the magnitude of the convection component of heat transfer.

Test Methods

The authors state that the power input was controlled to keep the sheath temperature constant and that both the sheath and ambient temperatures were controlled to maintain steady-state heat-flow conditions. The actual power input was obtained by measuring the energy input over a period of three to six hours. If the rate of heat transfer were accurately proportional to the temperature differences, this would be an entirely justifiable method. However, due to the nonlinear relations involved, the validity of an arithmetic average for the input power is questionable. Moreover, it would have been far simpler to keep the input power and the ambient temperature constant for a given run and to let the sheath temperature fall where it would.

R. W. Burrell (Consolidated Edison Company of New York, Inc., New York, N. Y.): The data presented by the authors are of considerable interest to cable engineers, and the Johns-Manville Company and the authors are to be congratulated for the presentation of this data. The painstaking care used in making these tests is commendable. The results would have been of still greater value if the tests could have been carried out on more than one cable size or at least on a more representative combination than a $3^1/_2$-inch cable in 4-inch duct. The data presented contribute significantly to our understanding of the thermal drop from cable sheath to duct wall. Of particular interest are the polar graphs of Figures 10 to 11 of the paper showing the temperature distribution around loaded duct walls. A need for further exploration of this phenomenon is indicated when these data are compared with the values shown in Figure 1 of Mr. F. V. Smith's discussion of a paper by J. H. Neher[1] presented in 1949. It should be noted that the temperatures given in Mr. Smith's discussion are outside duct wall values, but these show little departure from an isothermal surface in contrast with the values for outside wall shown in Figures 10 and 11 of the paper by Mr. Greebler and Mr. Barnett. Unfortunately, in the case of Mr. Smith's data, the heat loss per foot of cable, 3.0 watts, is relatively low for an average cable of a diameter of 2.52 inches. The comparison is also obscured by the possible variations as between single and multiduct structures.

There are a number of effects indicated in the data presented by the authors which

Figure 1 (left). Thermal resistance versus $\Delta T^{0.25}$ for fiber ducts

Figure 2 (right). Thermal resistance versus $(T_s + T_w)(T_s^2 + T_w^2) \times 10^{-9}$ for fiber ducts

Figure 3. Thermal resistance versus $\Delta T^{0.25}$ for Transite ducts

possibly may be taken as random deviation rather than true effect. In Figure 6 of the paper, the indicated change in thermal resistance from sheath to duct wall, for the case of fiber ducts in air, as between Series I and Series II, indicates the need for tests on a representative number of samples before firm conclusions can be drawn, although there is no doubt that the thermal resistance is higher in the case of dry fiber ducts as against Transite ducts.

The data on the volume thermal resistivity of Transite and fiber material are of interest. The average value for Transite is less than that formerly used by the Consolidated Edison Company in rating calculations, and we have adopted the lower value since these data were first released by the Johns-Manville Company some few years ago. The value for fiber is higher than our normal standard, and it is to be noted that the values derived from these tests are for the dry condition and may be appreciably lower when wet.

Considering the various values of β presented so far from different sources, apparently for the present we must accept a possible 10- to 20-per cent plus or minus variation in β for a given installation. Additional test data of the detailed type presented by the authors, on single and multiduct structures, in air and especially in earth, with cables of representative size and loading, are required before positive conclusions can be drawn.

R. J. Wiseman (The Okonite Company, Passaic, N. J.): This paper is a welcome addition to the investigation which has been going on in recent years as to the thermal resistance of duct systems. It, along with Mr. J. H. Neher's paper,[1] can well be studied for more exact thermal constants for ducts. Today there is a desire to obtain every ampere possible out of a cable. As the physical structure of the duct bank is important in determining the total thermal resistance of the duct bank, better knowledge of the influence of the kind of duct is desirable. The paper by Mr. Greebler and Mr. Barnett furnishes this information to us.

I wish the authors had used a heating load which would have given a sheath temperature of 40 to 45 degrees centigrade, as this is the range of temperature actually obtained in practice, and not the 82 degrees centigrade reported in the paper. We then would have obtained thermal constants more likely to exist.

In Table II of the paper the authors give thermal resistivity values. The value of surface resistivity for the lead sheath should be qualified that it is for a sheath diameter of 3.5 inches. Past tests indicate that it is actually a function of diameter. In the Insulated Power Cable Engineers Association we take cognizance of this by assuming that it increases from $\beta = 660$ ohms per square centimeter for $D = 0$, to 1,200 ohms per square centimeter for $D = 1.75$ inches and constant thereafter. According to Table II, these values may apply to fiber duct.

For Transite duct perhaps we should have a reduction of 15 to 20 per cent. The volume resistivity values for fiber duct, Transite duct, and concrete are very welcome. We have been taking a value of 100 thermal ohms per centimeter for concrete, so were on the conservative side.

F. H. Buller (General Electric Company, Schenectady, N. Y.): There are two points in connection with this paper which are particularly worthy of notice. All tests were taken on ducts in air, or encased in a concrete envelope situated in air, and the ends of the ducts were plugged up to prevent longitudinal convection. These statements also apply to the Barenscher investigation.[1]

Let us examine the significance of these points. Mr. Greebler and Mr. Barnett have presented curves (Series 2 tests) which show the effect of increasing the mass of concrete around the duct with the thought that the heavier mass of material simulated somewhat more closely the effect of underground burial of the duct bank. In this thought they are probably correct, and it will be noted from Figure 2 of the paper that the surface thermal resistance of the cable falls off materially in the case of the fiber duct and increases slightly in the case of the Transite duct, thus bringing these two types of duct closer together in their thermal properties. Presumably, burial in earth would exaggerate this effect further; it is quite possible, however, that such burial might ultimately reduce the values of surface thermal resistance in both cases below those given here for ducts in air. Further research is needed along these lines.

Moreover, it is noted that these tests were made on an isolated duct. There is reason to believe that in a multiple-duct bank, the value of β may be materially affected by the modification of the heat field in the duct structure by the presence of additional loaded ducts in close proximity, so that a test in air on a single duct is not necessarily representative of a multiple-duct bank buried in the ground.

The authors also have shown clearly that the drop through the fiber duct wall is greater than that through the Transite duct wall. However, these tests were taken on dry ducts. Presumably water saturation, which frequently occurs in the field, would tend to reduce the drop through the fiber

Figure 4. Thermal resistance versus $(T_s + T_w)(T_s^2 + T_w^2) \times 10^{-8}$ for Transite ducts

duct wall while affecting the Transite duct wall comparatively little.

Next, consider the question of plugging up the duct ends. The authors were undoubtedly justified in this procedure, since on such a short length of duct any appreciable longitudinal flow of air probably would have distorted observed results to a point where they became meaningless. However, it is not customary to seal up duct mouths in service, although it is sometimes done. Hence, in service, we may expect some longitudinal movement of air, which would tend to reduce the value of β below what was observed by the authors. Pipe cables, on the other hand, are necessarily sealed in service, since they operate under pressure.

These facts may explain, at least in part, the difference between the β values obtained by the authors and the lower ones observed in field tests on cable-installed underground in multiple-duct banks, notably those reported by Mr. Halperin.[2]

To sum the matter up, while it would appear that these tests were very carefully made, and while the technique used can probably be properly taken as a model for any future tests made on ducts in air, the results are not necessarily representative for the case of duct banks buried in the ground and operated under service conditions. They might possibly approximate more closely to the case of duct banks in air as sometimes used indoors in power stations and elsewhere.

J. H. Neher (Philadelphia Electric Company, Philadelphia, Pa.): This paper describes the procedure employed in obtaining the test results on cables in fiber and Transite ducts which I cited in my recent paper,[1] and which also appears in a paper by F. H. Buller and J. H. Neher.[2] I wish to compliment the authors of this paper on the thoroughness with which they have worked out this procedure, which may well serve as a model for future work along these lines.

Unfortunately, the tests were conducted with a single, and larger than average, cable size so that some extrapolation is necessary to convert the results to normal practice. The authors have attempted to do this in Figure 14 of the paper by expressing β as a function of the heat flow, but completely

Figure 5. Comparison of test data on fiber and Transite ducts in concrete

disregarding the effect of the cable diameter upon β. Mr. Buller and I have shown in our paper[3] that as a best approximation β is dependent upon the fourth root of the heat flow and the square root of the cable diameter.

Figure 5 of the discussion shows the data of Mr. Greebler and Mr. Barnett plotted as a function of the parameter $Q^{1/4}/D_s^{1/2}$ (Q in watts per foot; D_s in inches) together with the Barenscher[1] data for fiber ducts and the curve for cable in pipe given in the Buller and Neher paper.[2]

It should be noted that the Buller and Neher curve for fiber duct is based on the Barenscher data with which the fiber Series 1 test data of Mr. Greebler and Mr. Barnett is in fairly good agreement. Similarly, the Greebler and Barnett Transite Series 1 test data is so close to the cable in pipe curve that a distinction between the two is scarcely warranted. Only the Series I Greebler and Barnett tests were available to Mr. Buller and myself when our paper was prepared.

The second set of tests by the authors, falling as they do between the first tests on Figure 5 of the discussion, would seem to indicate that in the case of both fiber and Transite duct, β is a not too definite quantity ranging from 900 to 1,100 degrees centigrade square centimeters per watt for a typical cable installation in fiber duct and from 750 to 850 with a Transite duct.

I heartily indorse the authors' concluding paragraph to the effect that further tests along these lines would be valuable.

Paul Greebler and Guy F. Barnett: Probably the most common criticism of the test procedure arises from the fact that the sheath diameter employed was somewhat large. This cable size was taken from an actual installation in the field, but it is larger than that commonly employed in a 4-inch duct. The earlier experimental work by P. J. Barenscher,[1] as well as the more recent theoretical study by F. H. Buller and J. H. Neher,[2] indicates that the inverse relationship between the sheath diameter and the thermal resistance from the sheath to the duct is valid, as a good approximation, over an appreciable range of cable diameters. Additional tests on Transite and fiber ducts, using several smaller cable diameters, would add greatly to the value of these experimental and theoretical investigations.

Mr. Mason has presented data in his plots of R_{ia_1} versus variables in the convection and radiation terms that are very helpful toward understanding the mechanisms of heat transfer from the cable to the duct. We have not assumed in our paper, however, that the duct wall temperature is constant nor that the convection term is negligibly small. It was stated in the paper that variations in the convection term were small compared with those in the radiation term. This statement is verified by calculations carried out by Mr. Greebler in his discussion of a paper by Buller and Neher.[3] Values for R_{ia_1} were plotted against sheath temperature since this temperature is the principal variable in the thermal resistance from the cable to the duct for a given cable in duct geometry. Mr. Mason is entirely correct in pointing out that the arithmetic average of a periodically varying power input does not necessarily give the same results as an equivalent constant-power input, since the relationship between thermal resistance from cable to duct and power input is not linear. In our tests, however, the periodic power fluctuations were very small compared with the average input power, justifying the use of the latter as a highly accurate first-order approximation.

Mr. Burrell has discussed the polar graphs of Figures 10 and 11 of the paper showing the temperature distribution around loaded duct walls, and has compared these with similar data presented by Mr. F. V. Smith in a discussion of a paper by Mr. Neher.[4] The temperature distribution around the duct wall depends upon all of the thermal and geometrical variables that affect the cable-to-duct resistance, and it would be influenced by the mutual heating effects in a multiduct structure. It is expected that considerable departure from isothermal-duct surfaces occurs in any practical duct installation carrying an appreciable load and employing nonmetallic ducts with the cables resting on or near the bottom of their respective duct walls.

Mr. Buller has pointed out several factors in field installations, which we could not duplicate in our laboratory tests, that would modify the heat field and, therefore, influence the value of the cable thermal surface resistivity β. These factors tend, in general, to lower the value of β, and so the values given in our paper are slightly on the conservative side when applied to current rating calculations in buried duct structures.

Both Mr. Burrell and Mr. Buller have discussed the influence of moisture on the thermal resistivity of the duct materials in the field. It is true that the presence of moisture would produce a decrease in the thermal resistivity of the duct wall. However, for design purposes it would appear advisable to base calculations on the limiting case of dry ducts because it is not uncommon to encounter such conditions in practice, particularly for extended periods during the summer months. For continuously submerged ducts, special experimental determinations may be justified and may be expected to show a significant reduction in the component from sheath to duct wall.

The tests described in our paper cover the range of cable sheath temperatures from 50 to 80 degrees centigrade for duct in air and 60 to 80 degrees centigrade for duct encased in concrete. Dr. Wiseman has pointed out that temperatures for cable sheaths obtained in practice are normally below the range of temperatures covered in our tests. It is pertinent to point out that more and more emphasis is being placed on emergency loading at allowable copper temperatures that, for example, may be as high as 96 degrees centigrade at 15 kv (Association of Edison Illuminating Companies). Under such conditions a sheath temperature of the order of 80 degrees centigrade would not appear to be unduly high. The thermal volume resistivity values given in Table II of the paper are essentially independent of temperature over the entire operating range, but the surface resistivities increase as the cable temperature is lowered. The surface resistivity values given in Table II of the paper were obtained by extrapolating the curves of Figure 14 of the paper to a heat flow of ten watts per foot. The β values thus obtained represent a sheath temperature near 70 degrees centigrade for ducts in air and below 50 degrees centigrade for ducts in concrete. Extrapolation of these values to lower sheath temperatures, assuming a linear relationship over the operating range, is justifiable as a good approximation. The departure from a linear relationship when extrapolating to a lower temperature should yield resistivity values slightly on the conservative side, since it is expected from theoretical considerations that the slope of a β versus sheath temperature curve would approach zero as the temperature is lowered.

Mr. Neher has pointed out that Figure

14 of the paper does not give a complete picture of the variation in β since the effect of the cable diameter is not included. It is unfortunately true that β varies in a rather complicated manner with sheath temperature, cable diameter, and the many other factors in the over-all heat flow path from conductor to ambient that affect the heat field and, therefore, determine the temperature drop from the sheath to the duct. On the fortunate side, however, all of these variables produce only small changes in β over normal operating ranges; and so β can be treated as a constant for a given duct material or pipe for most practical thermal calculations.

The authors of this paper do not agree with Mr. Neher that as a best approximation β is dependent upon the fourth root of the heat flow, and this divergence has been elaborated upon by Mr. Greebler in his discussion of a paper by Mr. Buller and Mr. Neher.[4] The value of β is determined by the temperature distribution in the air space between the cable and the duct, and in relationship to the duct variables, this is most intimately associated with the sheath temperature. The cable diameter is probably the second most important of the variables that affect the value of β. In order to take into consideration variations in β with sheath temperature and cable diameter, values of β are tabulated in Table I of the discussion for sheath temperatures ranging from 40 to 80 degrees centigrade and for cable diameter from 1.5 to 3.5 inches. Four cases are considered separately, namely, fiber duct in air, Transite duct in air, fiber duct in concrete, and Transite duct in concrete. Thermal surface resistivity values shown in the table for a 3.5-inch diameter cable are the averages of the two series of tests, with the assumption that linear extrapolation to 40 degrees centigrade is justifiable. Approximate values of β for cable diameters smaller than 3.5 inches were obtained by assuming that convection contributes 30 per cent of the total heat transfer from the cable to the duct and that variations in the cable diameter produce an appreciable effect only upon the convection component of the thermal conductivity of the air space from the cable to the duct. These calculations are based in principle upon an analysis given by Mr. Buller and Mr. Neher[3] in which the convection component of thermal conductivity is shown to vary inversely with the square root of the cable diameter. The thermal conductivity is just the reciprocal of the resistivity factor β, and the resistivity value for a cable diameter D_s is computed from that experimentally determined for a 3.5-inch diameter $\beta_{3.5}$ employing formula

$$\beta = \frac{\beta_{3.5}}{0.70 + 0.56 D_s^{-1/2}}$$

This formula is consistent with the assumption mentioned earlier in this paragraph, and the value of β thus obtained is associated with the same sheath temperature as the $\beta_{3.5}$ that is used in the formula. Table I of the discussion shows that a decrease in the sheath temperature of 20 degrees centigrade coupled with a 100 per cent increase in cable diameter produces an increase in β of the order of magnitude of 20 per cent for each of the four cases considered. These data substantiate the previous statement that for most practical calculations β may be considered as a constant for a given duct material in air or in concrete over the normal operating range of sheath temperatures. The values given in Table I of the discussion indicate, however, that averaging β values for duct in air and duct in concrete, as was done in Figure 14 and Table II of the paper, is not entirely justifiable.

The various discussions indicate that more experimental data are desired for a more complete investigation of the duct heating problem, and the authors heartily concur in this opinion. If our paper encourages additional experimental investigations and serves as a guide toward obtaining reliable data from such further work, it will have succeeded in its major objective.

Statistical Nature and Physical Concepts of Thyratron Deionization Time

H. A. ROMANOWITZ
MEMBER AIEE

W. G. DOW
FELLOW AIEE

THYRATRON tubes are often used in circuits in which the anode voltage is made positive a very short time after the tube has been extinguished. In such a circuit a thyratron may refire when the anode voltage is made positive, even though the grid potential is considerably more negative than the amount required to prevent firing in the static case with the same anode voltage present. In such an instance residual ions in the tube are responsible for the failure of grid control. These ions are present due to the fact that not enough time is allowed between tube extinction and the instant of reapplication of positive anode voltage for the ions to disappear from the interelectrode space.

The time required for the tube to deionize sufficiently to prevent breakdown upon reapplication of positive anode voltage, with normal operating grid bias voltage present, is called deionization time.

This critical time interval is a very important factor that places an upper limit on the operating frequency of apparatus employing thyratrons, such as inverters and frequency changers, and is a significant design factor in many timing circuits employing thyratrons.

Statement of the Problem

The objectives of the research reported herein have been:

1. To measure directly the time intervals, between thyratron extinction and recurring positive anode voltage, that are required to prevent loss of grid control under conditions in which variations of important parameters are concerned.

2. To observe directly, for each of many individual trials, the variation of a thyratron's anode voltage during extinction and subsequent reapplication of positive anode voltage, in order to investigate the statistical nature of the probability of refiring.

3. To study the data and results in the light of existing facts and theory with the purpose of attempting to explain new aspects of the problem.

The parameters affecting deionization time in a given thyratron are: grid potential, grid circuit resistance, amplitude of anode voltage in both positive and negative directions, anode current prior to extinction, and condensed-mercury temperature.

Experimental Procedure

The tube used was a Westinghouse type *KU-627* mercury-vapor thyratron. A dimensioned sketch of it is shown in Figure 1. The test circuit diagram is shown in Figure 2. By means of this circuit the anode potential of the thyratron under test, T_1, was suddenly driven negative while it was conducting. After a time delay that could be controlled, the circuit reapplied a positive potential to the anode.

T_2 and T_3 each represent four type *6L6* tubes in parallel; T_4 and T_5 are small control thyratrons, and T_6 is a *6L6*, the grid of which receives the actuating voltage of the circuit. The actuating voltage is the voltage that builds up across the 0.01-microfarad capacitor when the S_1 section of the multiple key switch is closed. The grid of T_6 is thus made increasingly negative; this causes a rapid reduction of plate current in the tube.

The effects of the reduction in plate current of T_6 are: the firing of T_4, which cuts off T_2 and thus reduces the plate current of T_1 to zero; and the firing of T_5, after a time delay controlled by VD_2, which brings T_2 well up above cut-off and thus provides a path for the current of T_1 if conditions are such that it refires. At the beginning of the test cycle T_1 and T_2 are conducting and T_5 is not.

If the deionization has progressed sufficiently during the time interval Δt between the firings of T_4 and T_5, T_1 will fail to refire when its plate is driven positive, and the plate to cathode voltage of T_1 will have the wave-form *A-B-C-D-E-F-H* as shown in Figure 3. If, however, deionization has not been sufficiently complete, T_1 will refire and its plate-to-cathode voltage will drop to the conduction value indicated at *G*. Refires usually occur, if at all, before the voltage reaches point *F*.

The voltage to which the plate is driven negative is controlled by power supply number 1. The value of recurring positive voltage that follows the removal of the negative plate voltage is adjusted by the resistors R_1 and R_3. The operating plate current of T_1 is controlled by R_5, and the voltage of the generator supplying the main bus.

In order that the screen pattern of the transient voltage could be seen and photographed, it was necessary to increase the beam current of the cathode-ray tube during its motion from left to right on the screen. This was accomplished by short-circuiting the intensity control potentiometer of the oscilloscope by means of contacts of a key switch. The contacts closed just before the plate of T_1 was driven negative and opened just after it was driven positive. Another contact started the single sweep of the scope at the proper instant.

Three relays in the circuit were energized by lifting the handle of the key switch after each test observation. They opened the plate circuits of T_4 and T_5, extinguishing them, and the grid circuit of

Paper 50-56, recommended by the AIEE Electronics Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N.Y., January 30–February 3, 1950. Manuscript submitted November 1, 1949; made available for printing December 27, 1949.

Figure 1. Dimensioned sketch of the Westinghouse type *KU627* mercury-vapor thyratron employed in the tests

T_1, allowing it to refire if it failed to do so during the test.

When photographs were made it was necessary to superimpose a timing wave upon the plate voltage pattern. In taking a picture of the plate voltage wave, the camera lens, mounted in an extension tube, was placed inside the small open end of a light-proof cone that covered the screen. The shutter was opened before the key switch was pressed and closed immediately afterward. Then the switch S_4 was turned to the oscillator side of the circuit and the key switch again pressed while the shutter was held open. The oscillator frequency and the oscilloscope gain and frequency control positions were the same for both exposures. Therefore, the sine wave gives correct values for time intervals.

The oscillogram in Figure 4(A) shows a typical condition in which the tube failed to refire. The elapsed time (about 270 microseconds) between extinction and the reapplication of positive anode voltage was at least long enough for deionization to take place sufficiently for the grid to regain control. It can be seen that after the plate voltage was changed from a negative to a positive value, with respect to the cathode, it stayed at that value for the remainder of the test cycle.

The oscillogram in Figure 4(B) was taken under the same conditions as Figure 4(A) except that the time interval allowed for deionization was shortened until the tube refired consistently when the positive voltage came back on the plate. The horizontal gain of the oscilloscope was increased somewhat in order that the pattern would not be so narrow on the screen. The same timing wave was used, and it is seen that the time interval was about 125 microseconds. Figure 4(C) is a print made of another negative on which was drawn a positive voltage peak, or "spike," to illustrate the visual appearance on the cathode ray tube screen. The rapid change in voltage when the peak occurs causes the brightness in that region of the screen pattern to be so low that, although it is clearly visible, it does not affect the film emulsion sufficiently to show more than an extremely weak trace which will not print. A great many of these patterns were observed as the time allowed for deionization was being changed through the critical range.

Figure 2. Diagram of circuit used for deionization time measurements

Figure 3. Types of plate voltage wave forms observed: At *B* the anode circuit voltage is driven negative to the *CD* value, extinguishing the tube. At *D* the anode circuit voltage is driven positive to the *FH* value. Consequently, if the grid retains control, the shape *DEFH* is followed; if the tube refires, but at a low probability of refiring, the shape *DEFG* is followed; if the tube refires, but at a moderately high probability of refiring, the form *DEG* is followed

With medium, and also with comparatively long, time interval settings the voltage wave is rectangular, and the horizontal segment, when the plate voltage is negative, may be used as the time interval indicator on the scale. When the interval is short the lower left hand corner of the wave pattern is rounded off as in Figure 4(C), because the time required for the plate voltage to go negative is an appreciable part of the total time interval.

Readings were taken mostly by observation of repeated wave forms. Many repetitions of screen patterns were made at each circuit setting when data were to be recorded. This was desirable because the positions on the scale at the beginning and at the end of the pattern had to be determined so that the number of timing wave cycles taken up by the deionizing period could be accurately determined. It was deemed necessary that at least four or five successive identical patterns be obtained before the scale readings were considered reliable. The key was pressed at time intervals of about two to three seconds. The error in these observations is estimated to be about 6 per cent.

The time interval value recorded as the deionization time was the time interval corresponding to zero per cent refires.

Figure 4. Oscillograms

(A) Nonrefiring plate voltage oscillogram, of the type *A-B-C-D-E-F-H*, Figure 3. Typical record for conditions producing zero refire probability. 10,000 cycles per second timing wave

(B) Refiring plate voltage oscillogram, of the type *A-B-C-D-E-G*, Figure 3. Typical for conditions producing just about 100 per cent refire probability. 10,000 cycles per second timing wave

(C) Barely refiring plate voltage oscillogram, of the type *A-B-C-D-E-F-G*, Figure 3. Typical refire record for conditions producing very small refire probability

From an engineering viewpoint that is the minimum time that must elapse before the plate is again made positive.

Statistical Nature of the Results

In the explanation of the method employed in measuring the time interval, it was pointed out that the time interval that resulted in zero per cent refires was

Figure 5. Deionization time versus grid circuit volts, Westinghouse *KU627* mercury-vapor thyratron, anode circuit voltage driven abruptly negative to −200 volts, then abruptly positive to +200 volts. Grid resistor 5,000 ohms, condensed-mercury temperature 52 degrees centigrade. Parameter is anode current prior to driving anode voltage negative

Figure 6. Deionization time versus the anode current prior to driving anode negative; grid circuit voltage is the parameter. Same data as Figure 5

selected as the deionization time for that set of operating conditions. However, it was found that when slightly shorter time intervals were allowed for the deionizing process the application of positive voltage to the plate resulted in some refires and some failures. The percentages of these two kinds of behavior in a given series of test trials could be varied at will by varying the time interval. A study of the statistical nature of tube refires forms one of the most interesting and important parts of this study. The procedure followed in taking the statistical data now will be described.

As an example, suppose statistical data are to be obtained at a given set of operating conditions. The parameters held constant would be anode current, grid bias voltage, grid circuit resistance, condensed mercury vapor temperature, value of suddenly applied negative anode voltage used to extinguish the tube and maintained on the anode during deionization, and the positive voltage value to which the anode was suddenly raised.

The procedure followed was to start with a time-interval setting that produced 100 per cent refires. The voltage divider, VD_2 in Figure 2, would be in a relatively high position and control thyratron T_2 would fire shortly after T_1 fired.

Starting from a 100 per cent refire condition, the slider was lowered a little at a time until a refire or two was observed in 25 or 30 consecutive trials. At this point increments of upward movement of the sliding contact on VD_2 were employed until not a single failure to refire was observed in a series of 50 consecutive trials. The time interval for this setting of VD_2 was then measured, and was taken as the longest time that would result in 100 per cent refires. This was the value used to locate the topmost point on this particular probability curve, as for example any one of the curves in Figure 9.

To determine the shortest time that would result in 0 per cent refires, the VD_2 slider was lowered until refires were very scarce, then a final setting was made so that not one refire was observed in 50 consecutive trials. The time interval measured for this setting determined the location of the lowest point for this particular probability curve. This time interval was considered to be the deionization time for the particular tube operating conditions employed.

Intermediate points on the probability curves were obtained by setting VD_2 to give some desired percentage of refires, and then the time interval for that setting was measured. The intermediate per cent refires most commonly looked for were 5 per cent, 50 per cent, and 95 per cent.

Figures 5, 6, 7, 8, 20, and 21 are self-explanatory charts of the dependence of dionization time, measured as described before, on various experimental conditions. For explanations of the behavior displayed, see later discussions of happenings in the dying plasma.

Figures 9, 10, 11, and 12 are families of probability curves for various experimental arrangements.

It can readily be appreciated that many thousands of trials, that is, cycles of circuit operation, were required for each set of probability curves. Several hundred trials were usually required to obtain data for a single statistical curve.

Except for the 0 per cent and 100 per cent refire cases, the points were located from data taken with 40 to 50 trials each. A set of curves showing the effect of grid circuit resistance, for instance, obviously would be obtained by taking data for a complete curve, keeping the resistance constant at a particular value, and then repeating the procedure for each of the other values of resistance selected.

Happenings in the Plasma During Deionization

First Event—Plate Driven Negative

Early Conditions in the Plasma. At the moment that the plate is driven negative (dashed curve in Figure 13(A)), the input of energy tending to maintain the plasma electron temperature ceases. Also, the negative potentials on grid and plate make it impossible for plasma electrons to reach either grid or plate.

Therefore, immediately after the plate is driven negative, the plasma potential drops from its normal value (perhaps ten volts above the cathode) to approximate equality with the cathode; see the solid-line curve in Figure 13(A). O. E. Johnson and L. Malter, in a paper presented before the American Physical Society in Chicago, Ill., November 25, 1949, demonstrated that the electron temperature drops, with almost equal rapidity, to approximately the cathode temperature. The reason for this change is that a Boltzmann-relation electron exchange equilibrium is established at once between cathode and the dying plasma because the plasma cannot deliver electrons either to grid or plate. The equilibrium is not precise because the electron flow to the cathode must exceed that from the cathode by about the amount of the total ion current delivered by the plasma to grid and plate; however, this total ion current is a very small fraction of the equilibrium-condition electron exchange between cathode and dying plasma. The plasma existing during deionization will sometimes be called a rest-plasma.

Thickening of the Sheaths.[8,2] For purposes of discussion consider that the plasma drops to cathode potential, and the plasma electrons to cathode temperature, as soon as the anode goes negative. Ions are passing out of the rest-plasma to the grid and the plate, through the sheaths adjacent to those electrodes.

In a mercury-vapor thyratron of the type here employed, and under normal use conditions, the mean free paths of electrons and ions are several times the interelectrode distances. Therefore, the long-mean-free-path type of study is involved. Ambipolar diffusion considerations do not apply, because ambipolar diffusion is a characteristic feature of short-mean-free-path conditions.

In this plasma ion and gas temperatures will be equal, because the mechanism that raises plasma ion temperatures above gas particle temperatures is that of ion collisions; however, very few collisions occur, because free paths are long.

No new ions are being produced because the electron temperature has fallen to too low a value to give rise to ionization. It is not difficult to show analytically that under these conditions the ion concentration is uniform throughout the rest-plasma, that the rest-plasma is an equipotential region between the sheaths, and that the following equation expresses at any instant the ion current density through the sheaths

$$J_{ri} = \frac{N_i \alpha_g q_g}{2\sqrt{\pi}} \qquad (1)$$

Here

J_{ri} = random ion current density in the plasma,[3] and therefore ion current density through the sheaths;

N_i = ion concentration, also the electron concentration, in the plasma;

α_g = the particle velocity characteristic of the gas and ion temperature T_g, for particles of mass m_g, given by

$$\alpha_g = \sqrt{\frac{2kT_g}{m_g}} \qquad (2)$$

K = the Boltzmann gas constant, 1.372×10^{-23} joule per particle per degree Kelvin

All equations are in meter-kilogram-second units.

Under these conditions the sheath thickness will be given by s in the familiar 3/2 power equation[8]

$$J_{ri} = \frac{2.33 \times 10^{-6} E_s^{3/2}}{\sqrt{m_g/m_e}\, s^2} \qquad (3)$$

where

E_s = potential difference across the sheath.
s = sheath thickness.
m_g/m_e = ratio of gas-particle mass to electron mass; for mercury $\sqrt{m_g/m_e} = 610$.

Obviously as ions run out to the cathode, grid, and plate, N_i will become less and J_{ri} therefore smaller; thus from equation 3 the sheath thickness s must increase. Thus the condition of Figure 13(A) changes in due course to that of Figure 13(B).

In some measurable number of microseconds the sheath will become thick enough to fill the holes in the grid; immediately a new set of conditions appears.

Grid-Plate Plasma Drops Below Cathode Potential. The grid-cathode rest plasma remains at or near cathode potential indefinitely, as the cathode is the least negative adjacent electrode. As long as the sheath has not closed the holes in the grid, a conducting path exists between the

Figure 7. Deionization time versus value of grid resistor; grid circuit voltage the parameter. Anode circuit voltage driven abruptly to −150 volts, then abruptly to +150 volts. Anode current 200 milliamperes prior to driving anode voltage negative. Condensed-mercury temperature 58 degrees centigrade

Figure 8. Deionization time versus condensed-mercury temperature; grid circuit voltage the parameter. Anode circuit voltage driven abruptly to −200 volts, then to +200 volts. Anode current 300 milliamperes prior to driving anode negative. Grid resistor 3,000 ohms

Figure 9. Experimentally observed probability of refire versus time allowed for deionization; grid circuit voltage the parameter. Anode circuit voltage driven abruptly to −200 volts, then to +200 volts. Anode current 300 milliamperes prior to driving anode negative. Grid resistor 5,000 ohms. Condensed-mercury temperature 55 degrees centigrade

Figure 11 (right). Same as Figure 10, except that grid circuit voltage is −50

two plasma regions, and they remain at a common potential, about that of the cathode. As soon as the sheath does close the holes in the grid, the potential of the grid-anode plasma begins to drop; see Figure 14. The reason for this is that positive ions are continually running out, and if electrons cannot pass to the grid, the grid-anode plasma potential must drop because of the continuing removal of positive charge. The potential assumed by the grid-anode plasma at any instant will be such as to allow electrons to escape through or to the grid, or to the plate, just rapidly enough to balance the loss of ions.

The potential curves in Figure 14 are similar in nature to those familiar from a study of potential distributions in a high-vacuum parallel-plane triode. Thus the potential lines through points D represent the potential distribution along the axis of a grid hole; they are maximum-potential profiles for the region of the hole. The potential at D represents the low-potential barrier that any grid-plasma electron must be able to pass in order to escape to the grid-cathode plasma. The potential lines dropping from the plasmas to the faces of the grid describe the potential distribution through flat portions of the grid sheaths; these are minimum-potential profiles.

Qualitatively, in relation to Figure 14(B), one may think of the grid-cathode and grid-anode plasmas as establishing the plate and cathode potentials respectively (note the order) of a high-vacuum triode, whose grid potential E_g is just about that to produce cut-off, that is, limitation of leftward electron flow past D to a very minute amount.

In Figure 14(A) the sheath thickness s is barely more than enough to occlude the grid holes; by means of a drop of grid-anode plasma potential to a few volts below cathode potential, the electron-blocking potential minimum along the hole axis is almost eliminated. Thus just enough high-random-energy electrons to balance the ion loss from the grid-anode plasma are able to escape past this dip. In Figure 14(B) the sheath is thick enough so that a very substantial drop of grid-anode plasma potential is necessary in order to make the along-hole-axis potential dip E_d little enough to permit the escape of the necessary few electrons past it.

The grid-anode potential will never drop below its value in Figure 14(C), because to do so would cause a large electron flow to the grid, again raising its potential. Thus the grid-anode plasma potential cannot fall below that of the grid. Similarly it cannot fall below anode potential.

In principle then, after the grid holes are closed, the potential of the grid-anode potential falls, more or less abruptly, to a value differing very little from that of the least negative adjacent electrode. E. O. Johnson and L. Malter have demonstrated this experimentally. They have also shown, by a method of experimentation suggested by W. G. Dow, that the electron temperature in the grid-anode rest plasma drops to about room temperature as soon as the two rest plasmas become separated potential-wise.

Thus after grid-hole closure the potential distribution resembles one of the other of those in Figure 15(A), depending on whether or not the anode potential is below that of the grid. There are two important grid sheaths, one adjacent to the anode, the other adjacent to the face of the grid nearest the cathode.

In due time all of the electrons run out, leaving a distribution like that of Figure 15(B); the sheaths occupy the entire tube. Eventually all the ions run out leaving the typical space-charge-free distribution illustrated by Figure 15(C).

In summary, note that (1) for a time the grid holes are open, and the grid-anode and grid-cathode plasmas have a common potential; (2) after the sheaths fill the grid holes, the grid-anode plasma drops, approximately, either to grid or to anode potential; (3) after considerable time the sheaths fill both regions during transition to the space-charge-free condition ultimately existing if the anode remains negative indefinitely.

Second Event—Plate Driven from Negative to Positive

Gride-Anode Plasma at Cathode Potential when Anode Swings Positive. If, before the sheath fills the grid holes, the

Figure 10. Experimentally observed probability of refire versus time allowed for deionization; grid resistor the parameter. Anode circuit voltage driven abruptly to −150 volts, then to +150 volts. Anode current 200 milliamperes prior to driving anode negative. Grid circuit potential −6 volts. Condensed-mercury temperature 58 degrees centigrade

Figure 12. Experimentally observed probability of refire versus time allowed for deionization; condensed-mercury temperature the parameter. Anode circuit voltage driven abruptly to −200 volts, then to +200 volts. Anode current 300 milliamperes prior to driving anode voltage negative. One set for a grid circuit voltage of −150, another for a grid circuit voltage of −15 volts. Grid resistor 5,000 ohms

Figure 13. Potential distribution in the plasma

(A) At the moment the plate is driven negative, the plasma potential is unchanged; a sheath is established adjacent to the anode as in the dashed-line distribution. Immediately thereafter the plasma potential drops to a value such that its net loss of electrons to the cathode just equals its loss of ions to all electrodes; this potential is approximately that of the least negative adjacent electrode, in this case the cathode as shown in the solid-line distributions. The electron temperature quickly drops to thermal equilibrium with the cathode temperature

(B) Considerably later than (A); grid and anode sheaths have thickened substantially, but the plasma is still continuous through the holes in the grid

Figure 14. Decline of potential of grid-anode plasma following closure of grid holes by thickening of the grid sheath. The change from (A) to (B) to (C) is a consequence of the continuing thickening of the grid sheath. In each case the grid-anode plasma is low enough to make the grid-hole negative dip little enough so that the rate of electron escape to the cathode-grid plasma just equals the rate of ion loss from the grid-anode plasma to the grid and anode

(A) Shortly after sheath due to full grid potential is thick enough to fill grid holes

(B) Sheath somewhat thicker than for (A)

(C) Lowest potential reached by grid-anode plasma; this is the potential at which electron loss to an adjacent electrode just equals the ion loss. This potential is approximately that of the least negative adjacent electrode, which might be either grid or anode. As shown here it is the grid

Figure 15. Potential distribution changes during the deionization process, as during CD in Figure 3

(A) Illustrative potential distributions after grid-anode plasma potential has stabilized at a potential about that of the least negative adjacent electrode, which is the anode for curve A, the grid for curve B. Arrows H point to potential distribution through the grid holes, arrows M show it through the grid metal. Along curve B the grid sheath has disappeared of course, because the plasma is at grid potential

(B) Considerably later than (A); the sheaths occupy almost the entire interelectrode space; all electrons have run out, either to the cathode or the grid

(C) Considerably later than (B); all the ions have run out, leaving a typical space-charge-free potential distribution, shown along paths through and between grid holes

anode is abruptly driven positive, there exists a direct path for electron flow from cathode to anode, and the tube immediately refires; thus the least possible time to recovery of grid control is the time required for the sheath to fill the grid holes.

Grid-Anode Plasma below Cathode Potential when Anode Swings Positive. Consider that the potential of the plasma on the anode side of the grid is well below cathode potential at the instant the anode suddenly swings positive; see Figure 16 (A). Electrons pour into the anode from the plasma raising the rest-plasma potential on that side. As shown in Figure 16(B), the sheath on the anode side of the grid is re-established. The electron flow through the grid holes stops. At the instant the plasma potential on the right reaches cathode potential, the holes are still firmly closed, Figure 16(C). A fraction of a microsecond later the plasma potential is well above cathode potential, but the holes are still closed by a negative dip, Figure 16(D). This is followed immediately by the situation shown in Figure 16(E), which results in refiring of the tube. The behavior just described corresponds to Figure 4(C), and to the pattern *A-B-C-D-E-F-G* on the Figure 3.

The operation just described can be thought of qualitatively as being similar to the action in a high-vacuum triode having as its cathode the plasma face of the sheath to the left of the grid, and as its anode the plasma face of the sheath to the right of the grid, in Figures 16(D) and 16(E) particularly. In Figure 16(D) this triode is still below cut-off; in Figure 16(E) its plate potential has risen above cut-off.

If the sheaths are thicker, as in Figure 17, there may still exist, for a high recurring anode voltage, a negative dip along the grid axis; the comparable triode does not rise above cut-off. In that case the tube does not refire; as time passes the

Figure 16. Changes in potential distribution during change of anode potential from a strongly negative to a strongly positive value causing refire, as at moment *D–F* along *D-E-F-G*, Figure 3

(A) Anode potential has just started up from its position as along curve B in Figure 15(A), re-establishing a small sheath on the anode side of the grid, so re-establishing a negative dip and preventing further electron drainage toward the cathode. Grid-anode potential is that of the least-negative adjacent electrode, in this case the anode

(B) A fraction of a microsecond later than (A); anode potential still rising. Note the pronounced negative dip through grid holes

(C) Rising anode potential becomes equal to cathode potential; electrons cannot move between the two plasmas because of the negative dip through the holes in the grid

(D) Rising anode potential has substantially lifted the bottom of the dip in grid holes, but not enough to permit electrons to flow to the right, past it

(E) Tube will fire immediately, as at *F* along *D-E-F-G* of Figure 3, because the anode potential has lifted the grid-anode plasma high enough to eliminate the dip

Figure 16 (continued)

Figure 17. Anode potential the same as in Figure 16(E), but with a greater sheath thickness because of later voltage recurrence; the negative dip remains after complete recurrence of anode circuit voltage, as long *D-E-F-H* in Figure 3. Electrons have nearly all run out of the grid-anode plasma

electrons and ions run out, with eventual transition to the space-charge-free condition of Figure 18.

The Unique Time Interval. The points of view so far presented lead to certain indications, as follows:

1. There is a unique time interval, the time required for the sheaths to occlude the grid holes. If the anode voltage is driven positive before the elapse of this unique time interval, the tube will certainly refire at the moment the rising anode potential reaches a value a very little above the cathode potential. If more than the unique time interval has elapsed, refire will not occur until the anode has risen appreciably above cathode potential, and it may not occur at all, depending on the details of the cut-off action of the triode analogue to the grid-sheath combination. A high recurring anode voltage may cause refire to occur when a low recurring anode voltage will not; see Figure 21.

2. The unique time interval is independent of the potential to which the anode is driven negative in the first event, because the rate of loss of ions in either region is, to a first approximation, independent of the potential of the adjacent electrodes. Therefore, the deionization time should be independent of the potential of the anode during the dark period of the deionization test cycle. This agrees with experiment; see Figure 20.

3. The unique time interval is dependent on the grid potential, being less when the grid potential is low (that is, strongly negative). This is, of course, because a large sheath potential will produce a thick sheath even when the ion density is relatively large. This expectation is verified experimentally; see Figure 5.

4. Consider a circumstance in which the sheaths on the two sides of the grid are of unequal thickness due to unequal volume-to-surface ratios for the two regions. The question arises: which sheath thickness determines whether the holes are closed for the moment when the anode potential has risen just to equality with that of the cathode-grid region? Although no firm proof of the answer is presently available, the general concepts of space potential distribution, as in the analogous high-vacuum triode, suggest that with the two plasmas at a common potential there will exist a negative potential dip on the hole axis whenever the thicker of the two sheaths appreciably exceeds the half-diameter of the hole in thickness. This implies that the deionization time should depend on the rate of loss of ions in the most rapidly decaying of the two plasmas, in this case the grid-anode plasma. Figure 23 tends to support this conclusion.

Effect of the Grid Resistor. At the moment of anode voltage recurrence the grid current consists of ion current from both rest plasmas. Grid potential, relative to the cathode, is raised (made less negative) by the grid current voltage drop through the grid resistor. Thus the presence of a grid resistor makes the actual grid potential a function of time during the dark period, because the ion currents are declining during this period.

The following discussion, relative to Figure 19, illustrates the effect of a grid resistor on grid sheath thickness. Arbitrary voltage values are used. Curve E_{so}, Figure 19, shows the sheath potential required to prevent firing. Curve E_{gr} shows the approach of the actual grid voltage to the grid bias voltage E_{go}, as the ion-borne grid current declines during the dark period. If at a moment of anode voltage recurrence $E_{ao}+E_{gr}>0$ (of course, E_{gr} is negative) the tube will refire, as E_{gr}

then cannot produce the required sheath. Without a grid resistor, the corresponding criterion is that $E_{s0}+E_{g0}>0$.

At moment T_1, $E_{s0}+E_{g0}=50>0$, and $E_{s0}+E_{g0}=30>0$, so that the tube will refire either with or without a grid resistor. At T_2, $E_{s0}+E_{g0}=+5>0$, whereas $E_{s0}+E_{g0}=-10<0$; the tube will refire with a grid resistor, but will not refire without a grid resistor. At T_3 refire will not occur, either with or without a resistor. Thus the presence of a resistor increases the time required to come to the conditions that prevent refiring, so that use of a large grid resistor should give rise to a long deionization time. This is in accord with the experiments; see Figure 7. The grid resistor similarly has, indirectly, an effect on the recurring anode voltage necessary to cause late refiring; see Figure 21.

Analytical Determination of Deionization Time

The total ion content is volume V of the plasma multiplied by ion density N_i. The change of ion content in time dt is the electrode area presented to the plasma times

$-\frac{N_i\alpha_g}{2\sqrt{\pi}}dt$. The negative sign indicates a loss.

Note that

$$d(\text{volume}\times N_i)=-\text{area}\times\frac{N_i\alpha_g}{2\sqrt{\pi}}dt \tag{4}$$

Rewriting this

$$\frac{dN_i}{N_i}=-\frac{\text{area}}{\text{volume}}\times\frac{\alpha_g}{2\sqrt{\pi}}dt \tag{5}$$

Integrating

$$\log_e N_i=-\frac{\text{area}}{\text{volume}}\times\frac{\alpha_g}{2\sqrt{\pi}}t+\text{constant} \tag{6}$$

Figure 18. Many microseconds later than Figure 17, all electrons and ions have run out, leaving a space-charge-free potential distribution with a negative gradient adjacent to the cathode

Figure 19. Relations between grid potential and grid circuit potential during the deionization period; there is, of course, substantial grid current because of ion collection at the grid; this maintains the grid at a potential higher than the grid circuit potential. Thus a longer deionization time is required with a large grid resistor than with a small one

When $t=0$, $N_i=N_{i0}$ (plasma ion concentration before extinction). Therefore the constant of integration is $\log_e N_{i0}$.

$$\log_e\frac{N_i}{N_{i0}}=-\frac{\text{area}}{\text{volume}}\times\frac{\alpha_g}{2\sqrt{\pi}}t \tag{7}$$

$$\frac{N_i}{N_{i0}}=\exp\left(-\frac{\text{area}}{\text{volume}}\times\frac{\alpha_g}{2\sqrt{\pi}}t\right) \tag{8}$$

that is

$$\frac{N_i}{N_{i0}}=\exp\left(-\frac{t}{t_0}\right) \tag{9}$$

where

$$t_0=\frac{\text{volume}}{\text{area}}\times\frac{2\sqrt{\pi}}{\alpha_g} \tag{10}$$

which may be called the ion decay time constant.

Computation of t_0

The ion decay time constant will be computed for the tube used in the tests, for the grid-anode rest plasma and for the grid-cathode rest plasma, employing dimensions as shown in Figure 22. The volume and area occupied by the cathode are comparatively small and will be neglected. The anode will be treated as a surface one inch in diameter. The holes occupy 46.7 per cent of the grid baffle area.

The gas-and-ion temperature T_g is not definitely known, nor is it easily measurable. It is certainly higher than the temperature of the glass envelope of the tube and probably lower than the cathode temperature. It is not necessary to know T_g accurately in order to obtain a reasonable estimate of expected deionization time, partly because the temperature occurs only as $\sqrt{T_g}$, which tends to minimize the error due to the uncertainty as to its value. For the purpose of estimating t_0, a value of 1000 degrees Kelvin (727 degrees centigrade) will be used for T_g. Thus

$$\alpha_g=\sqrt{\frac{2kT}{m_g}}\cong\sqrt{\frac{2\times1.371\times10^{-23}\times1{,}000}{333\times10^{-27}}} \tag{11}$$

that is,

$$\alpha_g\cong287 \text{ meters per second} \tag{12}$$

For the grid-anode plasma:

$$\text{volume}=\frac{\pi}{4}\times1^2\times\frac{3}{8}\times(2.54)^3=4.82 \tag{13}$$

$$\text{Ion-receiving surface area}=\left[\left(\pi\times1\times\frac{3}{8}\right)+\left(\frac{\pi}{4}\times1^2\right)(1+1-0.467)\right](2.54)^2$$
$$=15.35 \text{ square centimeters} \tag{14}$$

$$\frac{\text{volume}}{\text{area}}=\frac{4.82}{15.35}=0.314 \text{ centimeter}$$
$$=3.14\times10^{-3} \text{ meter} \tag{15}$$

Therefore, using equations 10 and 12

$$t_0\cong\frac{3.14\times10^{-3}\times2\sqrt{\pi}}{287}=38.8\times10^{-6}$$

That is

$$t_0\cong39 \text{ microseconds, for the grid-anode plasma} \tag{16}$$

For the grid-cathode plasma, a similar calculation leads to

$$t_0\cong\frac{12.9\times10^{-3}\times2\sqrt{\pi}}{22.9\times287}=69.2\times10^{-6} \tag{17}$$

That is

$$t_0\cong69 \text{ microseconds, for the grid-cathode plasma} \tag{18}$$

The shorter period (for the grid-anode

Figure 20. Graph showing that deionization time is independent of the magnitude of the suddenly applied negative anode voltage (value during C-D in Figure 3). The parameter is plate current prior to driving anode voltage negative. Grid circuit voltage, −16 volts; grid resistor, 5,000 ohms; recurring anode voltage, +200 volts (value of voltage during F-H in Figure 3)

Figure 21. Graph showing dependence of deionization time on recurring anode voltage (value during F-H in Figure 3). Anode in all cases driven negative to −200 volts, as during C-D in Figure 3

Other test conditions as follows:

	Anode Current Prior to Test, Milliamperes	Grid Circuit Voltage	Grid Resistor, Ohms

plasma) may be expected to control the deionization time.

Computation of Deionization Time

The ion current density to the grid at the instant the first event occurs is

$$J_{io}=\frac{N_{io}\alpha_g q_g}{2\sqrt{\pi}}=\frac{I_{go}}{A_g} \tag{19}$$

where I_{go} is the easily measurable grid current just before the anode is driven negative, and A_g is the ion-collecting area of the grid, considering both plasmas. Equation 19 can be written

$$N_{go}=\frac{2\sqrt{\pi}I_{go}}{q_g\alpha_g A_g} \tag{20}$$

At any instant t seconds later, and before anode voltage recurrence

$$N_i=\frac{2\sqrt{\pi}I_{go}}{q_g\alpha_g A_g}\exp\left(-\frac{t}{t_0}\right) \tag{21}$$

Also, from equations 1 and 3

$$N_i=\frac{2\sqrt{\pi}\times 2.33\times 10^{-6}E_a^{3/2}}{s^2\alpha_g q_g\sqrt{m_g/m_e}} \tag{22}$$

Combining the last two equations

$$\exp\frac{t}{t_0}=\frac{\sqrt{m_g/m_e}}{2.33\times 10^{-6}}\,\frac{I_{go}s^2}{A_g E_a^{3/2}} \tag{23}$$

This can be solved for t; with the half-diameter $d/2$ of the grid holes used for s, it then becomes

$$t=t_0\log_e\left[\frac{\sqrt{m_g/m_e}}{2.33\times 10^{-6}}\,\frac{(d/2)^2}{A_g}\right]-t_0\log_e\left[\frac{E_a^{3/2}}{I_{go}}\right] \tag{24}$$

where t_c is the time to closure of the holes, that is, the moment when the grid sheath thickness becomes equal to the radius of the grid holes, for a plasma of about cathode potential.

The area A_g in the above equations is the grid area exposed to both plasmas before the first event, and is

$$A_g=\left[\left(\pi\times 1\times\frac{11}{8}\right)+2\left(\frac{\pi}{4}\times 1^2\right)(1-0.467)\right]\times(2.54)^2=33.3 \text{ square centimeters} \tag{25}$$

Comparison With Experiment

A consideration of equation 24 for time t_c to closure of grid holes shows that E_a and I_{go} are the other variables. The first term on the right-hand side is a constant and becomes

$$39\times 10^{-6}\log_e\left[\frac{610}{2.33\times 10^{-6}}\times\frac{\left(\frac{0.103\times 2.54}{2}\right)^2}{33.3}\right]=461\times 10^{-6} \tag{26}$$

Equation 24 becomes, for the grid-anode plasma

$$t_c=461\times 10^{-6}-39\times 10^{-6}\log_e\frac{E_a^{3/2}}{I_{go}} \tag{27}$$

The similar relation for the gride-cathode plasma is

$$t_c=815\times 10^{-6}-69\times 10^{-6}\log_e\left[\frac{E_g^{3/2}}{I_{go}}\right] \tag{28}$$

The relations described by equations 22 and 23 appear as straight lines in the coordinates of Figure 23.

The time to closure of grid holes in a plasma at about cathode potential should correspond approximately to the 100 per cent refire condition in the statistical curves. To understand why this is true, note that refire may occur if the anode voltage recurs well after hole closure, but it will always occur if voltage recurrence happens before hole closure. Deionization time as used in this paper corresponds to the 0 per cent refire condition, for obvious engineering reasons; therefore, the deionization time should always be somewhat longer than the time to hole closure. This difference is much greater proportionally with large than with small grid voltages, for reasons associated with the facts brought out later in the discussion of possible mechanisms causing the statistical behavior; see also Figure 21.

If no grid resistance is employed the grid sheath potential E_s may be reasonably well identified with grid potential E_g, so that data for which $R_g=0$ may be employed for comparison with theoretical considerations. Thus the curve of measured deionization time is obtained by using the $R_g=0$ points of Figure 7, using $E_s=-E_g$, and employing values of I_{go} based on measured grid currents. The useful grid-current-grid-voltage data, for conditions prior to the first event, R_g being zero, are plotted in Figure 23(B). This exhibits the usual nearly constant grid current for strongly negative grid voltages with a sharp upturn at about $E_g=-15$, due to the onset of electron penetration through the sheath. In accord with established practice in plasma probe studies, the value of I_{go} used for $E_g=-6$ and $E_g=-8$ is the ion current, obtained along the dashed extrapolation shown in Figure 23(B).

The line on Figure 23(A) indicating measured time to hole closure is based on (1) two firm points, taken from Figures 10 and 11, at $E_g=-6$ volts and $E_g=-50$ volts, together with (2) the general observation from the data as a whole that there is relatively little difference between hole closure (100 per cent refires) and deionization time (0 per cent refire) for short closure times, but a very great difference for long closure times. Table I gives further data.

The significant aspects of the comparison in Figure 23(A), between the theory and the experimental results, are as follows:

1. The time to hole closure, and the deionization time for strongly negative grid voltages, make straight-line plots when represented as a function of $\log_e(E_a^{3/2}/I_{go})$. This is in accord with the results of previous experimenters and with the theory presented above.

2. The theory gives the correct order of magnitude of time to hole closure except for the extremely short times observed for strongly negative grid potentials.

3. As is to be expected, the experimental data represent behavior closer to that computed for the rapidly decaying grid-anode plasma than for the grid-cathode plasma.

4. The theory is incomplete in that it ignores volume ion-electron recombination and ignores the possible initial existence of gentle radial plasma gradients; both effects would speed up deionization during the first

Figure 22. Diagram showing surface to volume proportions, in connection with theoretical computation of deionization time

few microseconds after the first event. Significant volume recombination does not occur in an active plasma because of the high electron temperature, but it may occur in the rest plasma with its modest electron temperature. However, the rate of volume recombination ion loss varies inversely as the square of the ion density, so will decline much more rapidly than the density. Therefore, it will be important, if at all, only during the initial stages of deionization when the ion density is greatest. Over-all, it is seen that the difference between measured and computed time to hole closure is of the kind to be expected on the basis of known incompleteness of the standard theory presented above.

5. The zero-time-intercept, at $E_g = -158$ volts, of the computed hole closure curve, implies that at this grid voltage the grid sheath should be sufficient to fill the holes in the presence of an active plasma, thus interrupting the flow of plate current. This grid snuff-out is a familiar phenomenon in the type desirable, *2050* and *2051* thyratrons used for cathode-ray time axis circuits.

6. Note that the contributions of this paper to the theory are chiefly clarifications of concepts within a well-established framework. The theory consists basically of fairly obvious applications of well-known and relatively simple principles of plasma behavior. The extension to cover large-hole thyratrons, such as the *FG-57* and the *FG-95*, is straightforward in principle, but requires care in detail. Larger holes of course mean longer deionization times, other things being equal. On the other hand, any changes that reduce the current density in the active plasma, for given total current, will tend to shorten the deionization time.

Wave Forms of Anode Voltage

In the taking of statistical data it was found that the shape of that part of the voltage wave corresponding to voltage recurrence was very significant. The relation of these wave form details to the statistical curves will now be discussed.

The Spike

Each statistical curve, as for example in Figure 9, identifies a time interval which corresponds to the latter portion of the deionization period, during which the grid-anode plasma is at a potential lower than that of the cathode but not lower than that of the grid. Oscilloscope screen patterns for all refiring observations during this less-than-100-per-cent-refire probability period were characterized by a positive voltage peak, or spike, as shown in Figure 24(A) and in Figure 4(C). The spike had near-maximum height for the refire occurrences at the 5 per cent refire probability time setting. Refire observations at the 95 per cent refire setting exhibited a very small spike, as shown at *A* in Figure 24(B). The spike practically disappeared at the just 100 per cent refire setting (hole closure), and for still shorter time settings the pattern rounded off at *B* in Figure 24(B).

Figure 25 illustrates the nature of the variation of the anode voltage wave form for various positions along a statistical curve.

The Rounding Off of the Wave

The rounding off of the recurring voltage wave, as at *B* in Figure 24B, implies a certain behavior in the thyratron plate circuit. Figure 26(A) shows a simplified plate circuit diagram with a reversible supply voltage source. The supply voltage is initially +200 volts, as in Figure 26(A), changes abruptly to −200 volts, and after a few hundred microseconds reverts to +200 volts. The rounding-off shown in Figure 26(B) means that at the moment *TT'* the circuit potentials are as shown in Figure 26(C).

Note that at this moment the anode is 15 volts below cathode potential, yet there is a current $i = 215/R_L$ through the tube and R_L in the normal direction. The grid-anode rest plasma is momentarily acting as a generator delivering an electron current appreciably exceeding the normal load current against an opposing potential of 15 volts. This is the same type of behavior as occurs at the onset of electron current in the grid current characteristic, Figure 23(B). Note that this

Figure 23. Experimental and computed data

(A) Curves of time to closure of grid holes and deionization time plotted relative to the significant logarithmic parameter. For the experimental data the anode was driven abruptly to −150 volts, returned to +150 volts, pre-test anode current 200 milliamperes, zero grid resistance, condensed-mercury temperature 58 degrees centigrade

(B) Pre-test grid currents, corresponding to the experimental data of (A)

occurs only for time settings prior to hole closure so that the grid holes are open and both rest plasmas are at about cathode potential and have an electron temperature about that of the cathode.

As rest-plasma properties change during deionization the available electron current from the grid-anode rest-plasma becomes markedly less. Thus for curve *A* in Figure 24(B) the electron current to the anode is little enough so that the anode potential change keeps up with the change of supply voltage during reversal.

Statistical Behavior Mechanisms

The occurrence of spikes on the voltage wave form, as in Figure 24(A), is correlated with the condition of a low percentage of refires. The occurrence of these comparatively few refires in a given number of trials always seemed random in nature. For instance, they were as likely to occur early as late, or to be bunched or

Figure 24. Anode voltage wave forms

(A) With spike

(B) With no spike and with marked rounding-off on recurrence

separated, in any set of forty successive observations. An examination of potential distribution diagrams will indicate an explanation of the correlation between the occurrence of spikes and the low-percentage refire condition.

The diagram in Figure 16(D) suggests the potential distribution in the tube at an instant near the end of deionization, when the anode voltage is about +100 volts and is rising rapidly. The tube has not refired. However, the potential within the grid holes dips below the cathode-to-grid plasma potential; the tube cannot refire as long as this dip is pronounced enough to prevent the electrons of higher random energies from getting through to the grid-anode region.

In Figure 16(E), the anode potential has risen high enough to eliminate the dip; within less than a microsecond the tube will fire due to electrons passing from left to right in substantial volume. This is the condition at the crest of a spike.

In Figure 17, for the same electrode voltages and grid sheath potentials as for Figures 16(D) and 16(E), and again at the instant the rapidly-rising anode voltage is at 100, the dip is so deep that its bottom is rising relatively slowly. This time the tube will not refire because a residual dip will still exist when the anode potential levels off at +200 volts.

However, if in this case the anode potential were to go on past +200 volts and in another half microsecond or so reach +300 volts, the dip would be eliminated and the tube would refire. This explains the reason for the sensitivity to recurring anode potential when the time allowed for deionization is almost long enough to reduce the per cent refires to zero (see curves *A* and *B* in Figure 21).

This suggests that the randomness in the deionization time interval may be attributable to variations, from trial to trial, in the potential at the bottom of the dip for a given rising anode potential. Such a variation could result from relatively small random variations in the ionic space charge content and distribution in the immediate neighborhood of the largest hole in the grid. It is to be expected that the potential distribution as illustrated in Figure 16(D) is subject to local rapid irregular fluttering as a result of space charge changes similar in origin to plasma ion oscillations. The firing or not in a particular trial will then depend on whether the moment of reapplication of voltage coincides with a moment of low or high potential at the bottom of the dip. The concept of the phase position of the moment of voltage return, relative to a plasma ion oscillation situation, may be helpful in picturing the cause of the randomness.

Conclusions

1. It has been shown that deionization time is a statistical concept (see Figures 8, 10, 11, and 14); the spread of the randomness increases more rapidly than the deionization time.

2. The statistical behavior has been correlated with changes in the wave form of the recurring anode voltage (see Figure 25) and with a reasonably rational mechanistic explanation as to the origin of the randomness.

3. Clarifying concepts have been introduced relative to the theory of the dependence of deionization time on tube geometry and potentials, and the theory has been shown to be in reasonably satisfactory agreement with the experiments here described.

4. The nature of the dependence or otherwise of deionization time on grid potential, grid circuit resistance, condensed-mercury temperature, and anode voltage has been shown experimentally and satisfactorily explained.

Effect of Buck-Boost Voltage Regulator on Steady-State Power Limit

C. CONCORDIA
FELLOW AIEE

FOR a long time it has been known that use of a properly-designed generator voltage regulator can increase the steady-state power limit of a synchronous machine appreciably. A previous paper[1] showed how to calculate the magnitude of the possible gain in power limit and presented some data showing quantitatively the gain as affected by the characteristics of the voltage regulator used. From these data it would naturally be inferred that to obtain maximum benefit the alternator field exciter should be separately excited rather than self excited; that is, the alternator field exciter should derive its own field excitation from its voltage regulator and/or pilot exciter rather than from its own generated voltage. However, there have been developed voltage regulating systems that partake of most of the advantages of both kinds of excitation. A typical system is the buck-boost system, in which the exciter field is supplied in part from its own generated voltage and in part from a regulating machine, for example, an amplidyne, which bucks or boosts this voltage. Figure 1 shows such a system. The regulator output voltage is put in series with the exciter terminal voltage across the exciter field.

Interest in this case arises from the fact that the buck-boost regulator is coming into use in central station applications, and it is thus becoming more and more necessary to be acquainted with the possibilities of increasing power limits, still retaining the advantages of close voltage regulation, reliability, and small regulator power requirements possessed by the buck-boost system. The first applications of voltage regulators to improve power limits, made in connection with the previous study,[1] were to ship propulsion systems in which there was not nearly so much incentive to use a buck-boost system.

In this paper it is shown that by proper stabilizer design it is possible to increase the power limit practically as much with a buck-boost excitation system as with the previously-considered separately-excited system. In all the cases discussed here, the exciter field resistance and saturation lines have been assumed to be parallel, so that the over-all steady-state amplification factor is infinite, that is, the voltage regulation is zero.

Conclusions

1. For the power system considered, and with the addition of a proper stabilizer, the steady-state stability limit can be increased practically as much with a buck-boost regulator (having an infinite steady-state amplification) as with the separately-excited exciter considered in reference 1.

2. For best results with a stabilizer supplied only from exciter voltage, the stabilizer washout time constant should be at least of the same order of magnitude as the alternator field time constant (under load).

3. The stability limit may also be increased by the aid of a stabilizer supplied from alternator terminal voltage. In this case the stabilizer washout time constant need not be large. This conclusion does not necessarily imply that the terminal-voltage stabilizer is to be preferred, as there are additional obstacles to be overcome in the practical application of such a stabilizer.

4. The gain in power limit is not affected greatly by the magnitude of the stabilizing signal as long as it is sufficiently large.

5. Tests have confirmed that stable operation at powers greater than the unregulated steady-state limit is possible with a buck-boost voltage regulator.

Paper 50-57, recommended by the AIEE Power Generation Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted June 16, 1949; made available for printing December 1, 1949.

Analysis

POWER SYSTEM

The electric power system studied here is the same as that considered in detail in parts A of the "Analysis" and "Application" sections of reference 1. This same system also has been used in reference 2, for a comparative study of an angle regulator. As the same notation and assumptions used in references 1 and 2 are used here, the derivation of the system equations will not be repeated. The system consists of a synchronous machine connected through a tie line to an infinite bus.

Under equilibrium conditions, unity power factor and voltage are maintained at the terminals of the machine. The power system parameters are as given in equations 30 and 31 of reference 1, and also are given in Tables I and II of this present paper.

It is evident from the derivation given in reference 1 that the characteristic equation of the coefficients of the system variables in the differential equations representing the power system is

$$p^{5}2MT_e(1+x_d')\cos^3\frac{\delta}{2}+p^{3}\,2M\times\left[2-g(p)\ \cos\frac{\delta}{2}\right]\cos^3\frac{\delta}{2}+p^{1}T_e\times[(1+x_d')\cos\delta+(1-x_d')\sin^2\delta]+p^{0}\left[2\cos\delta-g(p)\cos\frac{\delta}{2}\right]=0 \quad (1)$$

where

$$\Delta E=g(p)\,\Delta e_t \quad (2)$$

is the regulating system equation relating the change of alternator excitation voltage ΔE to the change of alternator terminal voltage Δe_t.

Equation 1 is essentially the same as equation 32 of reference 1 and equation 12 of reference 2. Only this characteristic

Figure 1. Voltage regulating system

equation is necessary for the study of stability by Routh's criteria.[2]

Regulating System

The regulating system is shown in Figure 1. The alternator field is supplied by the exciter voltage E. The exciter field is in turn supplied by the exciter voltage E and the amplidyne voltage e_a. The field voltage equation is therefore

$$(T_e p+1) r_e i_f = E + e_a \tag{3}$$

where

$p = d/dt$ = the time-derivative operator
$T_e = L_e/r_e$ = exciter field time constant
L_e = exciter field inductance
r_e = total exciter field resistance
i_f = exciter field current

and the variables are considered to be small deviations from their equilibrium values in all of the regulating-system equations in this paper.

The slope of the exciter saturation curve is M_e, so that

$$E = M_e i_f, \text{ (or } i_f = E/M_e) \tag{4}$$

Substituting equation 4 in equation 3, and solving for E, we find

$$E = \frac{(M_e/r_e)e_a}{T_e p + 1 - (M_e/r_e)} \tag{5}$$

The amplidyne output voltage e_a is taken as equal to the regulator output voltage e_r with a single time lag T_a

$$e_a = \frac{e_r}{T_a p + 1} \tag{6}$$

The regulator output voltage e_r is proportional to the sum of the alternator terminal voltage deviation e_t and the stabilizer voltage e_s

$$e_r = a'(e_t + e_s) \tag{7}$$

There are two stabilizers, one supplied from the exciter voltage E and the other from the alternator terminal voltage e_t. The stabilizer output voltage e_s may be represented for the present purpose by the relation

$$e_s = -\frac{bT_b p}{T_b p + 1} E + \frac{cT_c p}{T_c p + 1} e_t \tag{8}$$

The stabilizers thus have the characteristic of transmitting a signal to the regulator during sudden changes or oscillations but no signal in the steady state.

Substituting equation 8 in equation 7, the regulator voltage e_r becomes

$$e_r = a'\left[\frac{(1+c)T_c p + 1}{T_c p + 1} e_t - \frac{bT_b p}{T_b p + 1} E\right] \tag{9}$$

From equation 6, the amplidyne voltage is

Figure 3. Effect of voltage regulator on steady-state stability limit. Effect of regulator time lag

$$e_a = \frac{a'}{T_a p + 1}\left[\frac{(1+c)T_c p + 1}{T_c p + 1} e_t - \frac{bT_b p}{T_b p + 1} E\right] \tag{10}$$

From equation 5, and with some rearrangement, the exciter voltage E is

$$E = \frac{a''(T_b p+1)[(1+c)T_c p+1]}{[(T_e p+1-R)(T_a p+1)(T_b p+1)+ a''bT_b p](T_c p+1)} e_t \tag{11}$$

where

$R = M_e/r_e$

and

$$a'' = (M_e/r_e)a' \tag{12}$$

The steady-state amplification factor of the regulating system is, from equation 11 with $p=0$,

$$\frac{E}{e_t} = \frac{a''}{1-R} \tag{13}$$

As stated before, in all cases considered, $M_e = r_e$ or $R = 1.0$, so the amplification factor is infinite. For this reason the maximum power limit has been plotted against a'', which is the amplification

factor which the same regulating system would have with a separately-excited exciter.

Complete System

To obtain the characteristic equation for the complete system, we recognize equation 11 as identical to equation 2, so the coefficient of e_t in equation 11 is substituted for $g(p)$ in the power-system equation (equation 1). The stability of the system as represented by this final equation has been studied by Routh's criteria, and the results are discussed in the following section.

Cases Studied

Exciter-Voltage Stabilizer

The results obtained with the exciter-voltage stabilizer acting alone ($c=0$) are shown in Figures 2, 3, 4, and 5, in which the maximum stable operating angles δ are plotted against the voltage-regulating-system separately-excited amplification factors a''. For the power system considered, the power P corresponding to any given operating angle δ is given by the formula[1]

$$P = \tan\frac{\delta}{2}$$

The power corresponding to any particular angle can thus be very simply determined. The system parameters are given in Table I.

Figure 2 shows the effect of the stabilizer washout time constant T_b. It is seen that the larger the time constant, the greater the power limit, but on the other hand the gain is small for increases of T_b beyond the value of the alternator field time constant, which under the present system conditions is $T_a\ (x_d'+x)/(x_d+x) = 1{,}300$ radians or about 3.5 seconds. This is more or less in agreement with the similar conclusion presented in references 4, 5, and 6. Curve C of Figure 1 of reference 1 also is plotted in Figure 2 of this paper as the Separately-Excited Case. It is evident that as the stabilizer washout time is increased the buck-boost case approaches the separately-excited case. This may be seen mathematically if in equation 11 we let T_b be infinite (with $c=0$, $T_a=0$, and $a''b=1$). The regulator equation then becomes

$$E = \frac{a''}{T_e p+1}\, e_t = \frac{a''}{400p+1}\, e_t \tag{14}$$

which is exactly the same as the separately-excited case of reference 1.

Figure 3 shows the effect of including in the calculations the effect of an additional time lag T_a in the amplidyne. As was expected, the region of stable operation is diminished somewhat.

Figures 4 and 5 show the effect of varying the magnitude of the stabilizing signal ($a''b$). The maximum power limit is slightly improved by a four-fold increase of ($a''b$), and the effect on the permissible range of regulating-system amplification factor depends on the amplidyne time lag.

The effect of $a''b$ shown in Figure 5 may be correlated with that previously observed in the separately-excited case by

Figure 6. Effect of voltage regulator on steady-state stability limit with terminal-voltage stabilizer

Effect of magnitude of terminal-voltage stabilizer signal

Figure 8. Effect of voltage regulator on steady-state stability limit with terminal-voltage stabilizer

Effect of removing exciter-voltage stabilizer

Table I. Exciter-Voltage Stabilizer

Case	Figure	T_b	T_a	$a''b$
A	2	200	0	1
C	2, 3, 5	1,000	0	1
F	2	2,000	0	1
G	2	4,000	0	1
E	3, 4	1,000	100	1
H	4	1,000	100	4
D	5	1,000	0	4

For all cases:
$x_d = x_q = x = 1.0$ $\quad r = 0$
$p.f._{norm} = e_{norm} = 1.0$ $\quad T_s = 2000$ radians
$x_d' = 0.3$ $\quad T_a = 400$ radians
$M = 4{,}000$ radians $\quad R = Me_s/\gamma = 1.0$

Note: As all values are in per unit, for a rated frequency of 60 cycles per second, the time constants in seconds are 1/377 times the numbers shown.

noting that with $a''b = 4$ and $T_b = \infty$ (with $c = 0$ and $T_a = 0$ as before), the regulator relation becomes

$$E = \frac{\frac{a''}{4}}{100p + 1} e_1$$

This means that the stability curve should lie between curves A and C of Figure 1, reference 1, except that the amplification factor a'' is multiplied by 4. Comparison of curve D of Figure 5 with curve A of Figure 1, reference 1 shows that this concept is a reasonable one.

Terminal-Voltage Stabilizer

The results obtained with the addition of the terminal voltage stabilizer are shown in Figures 6, 7, and 8. The system parameters are given in Table II.

Figure 6 shows the effect of the terminal-voltage stabilizer amplification factor c. The terminal-voltage stabilizer has been added to a system having already an exciter-voltage stabilizer with $a''b = 1.0$. The maximum power limit is increased considerably, but just as in the case of the exciter-voltage stabilizer, most of the increase is obtained by moderate values of the amplification factor c. Note that the stabilizer washout time constants $T_b = T_c$ are now only 200 radians or about a half second. In fact, we may observe that in order for the terminal-voltage stabilizer to have any stabilizing action it must have a reasonably small time constant, as equation 11 shows that with $T_c = \infty$ the only effect of c is to multiply the amplification factor a'' by $(1+c)$.

Figure 7 shows that the two stabilizer time constants can be decreased to 100 radians with only a slight loss in power limit. Curve L, having a maximum stable operating angle of about 108.5 degrees, also may be compared with curve C of Figure 2, which also has a maximum angle of 108.5 degrees and an exciter-voltage-stabilizer time constant of 1,000 radians, or five times as great as for curve C.

Figure 8 indicates that the exciter-voltage stabilizer can be eliminated and still an appreciable gain can be realized by use of the terminal-voltage stabilizer acting alone.

Correlation with Test Results

While no direct quantitative test check of the calculations presented in this paper has been made, the possibility of operation in the so-called dynamic-stability region (that is, operation at powers greater than the maximum possible with manual excitation control) with a buck-boost regulating system has been demonstrated by tests on an actual electric power system. These tests will be briefly described, since they show that operation beyond the normal steady-state stability limit can be demonstrated without exceeding tolerable limits of the test machine and without the necessity of involving long transmission lines.

In 1946, tests were made on a 20,800-kva hydrogenerator to obtain information regarding operation in the region of dynamic stability.

The procedure in making these tests was:

1. To arrange the station circuits so as to introduce maximum reactance between the system and the test machine.

Table II. Terminal-Voltage Stabilizer

Case	Figure	$T_b = T_c$	$a''b$	c
A	6	200	1.0	0
L	6, 7, 8	200	1.0	1.0
M	6	200	1.0	5.0
N	7	100	1.0	1.0
R	8	200	0	1.0

For all cases:
$x_d = x_q = x = 1.0$ $\quad T_s = 2000$ radians
$p.f._{norm} = e_{norm} = 1.0$ $\quad T_a = 400$ radians
$x_d' = 0.3$ $\quad T_a = 0$
$M = 4{,}000$ radians $\quad R = Me_s/\gamma = 1.0$
$r = 0$ $\quad T_b = T_c$

Note: As all values are in per unit, for a rated frequency of 60 cycles per second the time constants in seconds are 1/377 times the numbers shown.

2. To remove all compensation from the voltage regulator to be tested.

3. To put the other machines in the station on hand control.

4. To set the test machine load at about 50 per cent.

5. Finally, to reduce the terminal voltage level held by the regulator under test until the stability limit was reached.

This method of reaching the stability limit was followed since it appeared impractical to attempt to overload the test machine at its normal operating voltage. The power and reactive kilovolt-ampere limits of the machine would be greatly exceeded for pullout at normal terminal voltage. Even for pullout at half rated power the machine kilovolt-amperes and armature current ratings are exceeded to some extent.

As the voltage level at the machine terminals is reduced the field current decreases. This keeps up until the limit of stability with hand control is reached. If it is possible to operate in the dynamic stability region the field current will then increase as the voltage level is reduced further. The nature of this phenomenon is illustrated in Figure 9. In this figure, e_1 is the constant system voltage, and the

Figure 9 (left). Relations of machine terminal voltage and excitation

Figure 10 (right). Dynamic stability tests

Generator is in dynamic stability region for terminal voltage less than 10,000

various values of e_t are the machine excitations corresponding to operation at the various terminal voltages e_t. We have taken the simple round-rotor case wherein the total reactance is 1.0 per unit; 0.8 in the machine, and 0.2 in the system.

It is seen that the voltage drop caused by the power component of current i_p (the component in phase w'th the system voltage) remains constant at 0.5, since the power remains constant at 0.5, and only the reactive components i_x i_1, i_2, i_3 vary as the terminal voltage e_t is reduced. The amount by which the field current e_3 can increase from the minimum value reached as the terminal voltage is continually reduced is evidently a measure of the amount by which the hand-control steady-state power limit may be exceeded.

The armature and field current obtained in the tests as the terminal voltage was reduced are plotted in Figure 10. The field current first decreased to about 90 amperes and then increased to about 130 amperes, thus showing that the machine could operate in the dynamic-stability region with the buck-boost voltage regulating system as set for normal operation.

In order to interpret this test increase in field current in terms of increased power limit under more usual operating conditions, the significant effect of the regulator has been assumed to be to reduce the effective direct-axis reactance x_d of the machine, as discussed in reference 2. For example, if the voltage regulator maintained constant field flux linkages instantaneously, it would effectively reduce the machine direct-axis reactance x_d to the transient value x_d'.

The interpretation procedure has, therefore, been to calculate field current versus effective direct-axis reactance at the stability limit, for the system and load conditions of the test, in order to determine the effective reduced x_d produced by regulator action as indicated by the allowable increase of excitation. Then using this effective x_d the power limits for normal operating conditions are calculated and compared to the limits obtained with the actual x_d and x_d'.

Discussion

C. E. Valentine (Westinghouse Electric Corporation, East Pittsburgh, Pa.): There are a number of regulating machines, or rotating amplifiers, any one of which may be used as part of a voltage-regulating and excitation system for a synchronous machine. The buck-boost action of the rotating amplifier may be obtained by connecting the output terminals of the amplifier in series with the shunt-field winding of a self-excited exciter as shown in the paper or by connecting the output of the amplifier to an independent field on the exciter. The Rototrol buck-boost exciter is being used in the latter manner although it is capable also of application as a main turboexciter, in which case there is no pilot or buck-boost exciter.

When the Rototrol works into an independent field on a main exciter, it operates under the control of the voltage regulator to buck or boost the main exciter voltage by opposing or adding to the effect of the exciter self-energized field. There are time delays of differing magnitudes in the machine windings. These have to be taken into account, and the design of the rotating amplifier and the exciter co-ordinated to give the response which is required of the exciter for a given application.

This excitation system may be stabilized in a number of ways including those described in the paper, and is effective in improving the steady-state power limit of the synchronous machine.

A. Dovjikov (Bonneville Power Administration, Portland, Oreg.): The whole series of papers presented at this meeting indicates revived interest in problems of excitation, what excitation can accomplish, and the means to accomplish it. All papers indicate that the conventional system of excitation, consisting of main exciter, its pilot exciter, and of an automatic voltage regulator with its moving contacts, could be advantageously replaced by other forms of exciters, either of the electronic type or of the rotating-machine type. The fundamental difference of both types as compared with the conventional system is that the amount of power handled by the automatic voltage regulator is much smaller and therefore much more sensitive and faster types of static automatic voltage regulators may be used.

In the first applications of this new type of excitation, the emphasis was put on close voltage regulation, but it is only natural that the advantageous features of this new type of excitation were thought of when the problems of the operating engineer required faster excitation, for example, for an increase of steady-state and dynamic stability of the system.

The paper is a welcome contribution to this problem, but, although admirable in its highly mathematical analysis, it does not provide the operating engineer with curves or bands of numerical characteristics of this new development. We would be particularly anxious to see the sample oscillograms of this new excitation which illustrate different points of Mr. Concordia's considerations. Particularly interesting would be oscillographs of the speed of action and the effect of elimination of the exciter-voltage stabilizer. We always wondered whether the stabilizer across the exciter terminal voltage is not rather detrimental in cases where quick response of exciter terminal voltage is desirable because this stabilizer, as its name implies, tends to prevent too rapid variation of exciter voltage. It should be kept in mind that rapid variation of voltage of the exciter is desirable, not only from the stability point of view, but because it is also necessary in cases of load rejection, particularly with one or more long, high-voltage lines hanging on the station bus. The overvoltage on the generating bus due to generators' acceleration is one of the main factors determining the sealoff voltage of lightning arresters connected to this bus, and through that it determines the rating of the arresters and the basic insulation level of generating stations.

John G. Noest. (Consolidated Edison Company of New York, Inc., New York, N. Y.): In these days, whenever increasing costs put heavy economic pressure on the fullest utilization of equipment, new and greater emphasis is placed on any device which promises a step in that direction.

Automatic voltage regulation for synchronous generators is a subject of consistent interest to the industry because, when properly designed, it permits an increase in the steady-state power limits, in addition to its other, well-recognized advantages.

In the past there have been presented before the Institute a large number of papers dealing with this subject and these papers have, with increasing clarity and with greater precision, attacked the problem on a broad front and in its narrower ramifications. Through the use of powerful analytical methods, assisted by analogues and by modern calculating machinery, such as the differential analyzer, the regulating system characteristics which permit proper design are being disclosed.

The paper by Mr. Concordia is a sequel to two earlier papers[1,2] on the same general subject, and it extends the art to include the buck-boost type of regulating system.

In his paper, Mr. Concordia has shown that the buck-boost regulating system can accomplish, in regard to increasing the

steady-state stability limit, practically the equivalent of that regulation obtainable with separately excited systems. The buck-boost system accomplishes this with greater fundamental simplicity and greater economy of means.

It seems to me that with proper modification of the parameters and of the excitation system transfer function, $g(p)$ of equation 2 of the paper, the methods employed in the 1944[1] and present papers become directly applicable to the electronic type of excitation system as well.

To all engineers, and particularly to the younger men, Mr. Concordia's methods of attacking the problem should give great inspiration. The use of the operational method, together with the application of Routh's[2] and Hurwitz'[4] criteria in the determination of stability, permit the treatment of the problem with simple clarity and economy of effort.

E. E. Cobb (Ebasco Services, Inc., New York, N. Y.): What is the expected performance of a buck-boost voltage regulator when operating generator at 95-per cent leading power factor and 100-per cent load? Also, what will be the effect on stability during transient fault conditions?

C. Concordia: Mr. Dovjikov has pointed out in his discussion an important point that was perhaps not sufficiently emphasized in the paper; namely, that we are concerned in this paper with continuously-acting voltage regulators, that is, regulators having essentially no dead band, as distinguished from motor-driven rheostatic-control voltage regulators having a definite dead band. The continuously-acting regulator is practically a necessity if advantage is to be taken of possible steady-state operation beyond the unregulated power limit. We should not infer that such dynamic-stability operation is necessarily made possible by high rates of response. On the contrary, the usual rheostatic regulator has incorporated in its design the so-called high-speed contacts, which will permit high rates of response if the voltage deviation exceeds a prescribed band width, and there is no reason why with proper design the response cannot be as fast as with the continuously-acting type under this condition. A further advantage of the no-dead-band type is, of course, the possibility of closer voltage regulation, as Mr. Dovjikov has remarked.

In regard to oscillograms of response we call attention to Figure 8 of the paper by F. M. Porter and J. H. Kinghorn,[1] which shows the response of an amplidyne buck-boost voltage regulating system to a sudden change of regulated voltage level. On load rejection, either the buck-boost amplidyne regulator, even with an exciter-voltage stabilizer, or the rheostatic type with high-speed contacts, should give comparable performance; in this case the time to maximum voltage is rather long, that is, at least a few seconds.

Mr. Valentine has very properly pointed out that other types of continuously-acting voltage regulators can be made to give an improvement in power limit if properly stabilized. We have preferred to consider the rotating-amplifier buck-boost voltage to be inserted in series with the exciter field rather than on a separate field winding, as described by Mr. Valentine, for the reason that he himself mentions, namely, that operation through a separate field involves additional time lags.

Mr. Cobb has asked what is the expected performance of a buck-boost voltage regulator when operating a generator at 95-per cent leading power factor and 100-per cent load. This, of course, depends on system conditions, but in general we should expect no difficulty on the usual system. Such operation is discussed in a paper by C. G. Adams and J. B. McClure.[2] It need not, and in general does not, involve operation in the dynamic-stability region so that no special regulating system is required, but it is desirable that the voltage be under automatic control.

A rather complete discussion of the problems involved in leading-power-factor operation was given in a series of unpublished conference papers presented at the AIEE 1950 Winter Meeting.

The effect on transient stability of any properly designed voltage regulator should be beneficial but is in general rather slight, as the times involved are usually so small as to permit little change in generator field flux.

Moreover other factors, not involved in the calculation of steady-state stability, become pertinent, in particular, the exciter ceiling.

Mr. Noest's comments are appreciated. We particularly agree with him that the methods of this paper are directly applicable to the electronic type of excitation system.

In conclusion, we wish to thank all of the discussers for their contributions to this important subject.

Bus Transfer Tests on 2,300-Volt Station Auxiliary System

A. A. JOHNSON
MEMBER AIEE

H. A. THOMPSON
NONMEMBER AIEE

Synopsis: Transfer tests were made of one auxiliary bus section in a large power station from one source to another source. The two sources, one an auxiliary generator and the other a service transformer, were not paralleled during the transfer operation. The optimum open time interval was determined and inrush currents, voltage changes, and some power measurements were made on the combined bus load and on several individual motors. Successful transfers were made at time intervals up to about 150 cycles. The motors, the auxiliary generator, and the station boilers operated satisfactorily for all tests.

RELIABLE auxiliary power systems for steam power plants are indispensable, and at least two sources of power are usually available from which the auxiliaries may be supplied. In the event of failure of one source, the load can be transferred to the other. The manner in which a transfer is made affects the auxiliary feeder circuit breakers, feeder and bus protective relays, the motors, and other equipment in the station. Bus transfer tests made on the auxiliary power system of the Phillips Power Plant of the Duquesne Light Company give results which determine the optimum conditions for transfer. The relaying is not discussed in this paper.

Description of Test System

The Phillips Plant has one 75,000-kva turbogenerator with a 7,500-kva 2,300-volt, 3,600-rpm auxiliary generator on the same shaft with the main unit. The auxiliaries shown schematically in Figure 1 are divided into two major groups, and either group may be supplied from the auxiliary generator or from a 7,500-kva station service transformer. The auxiliary system includes all of the large motors for boiler and turbine service, the 440-volt power and station lighting. Normally one bus is connected to the station service transformer, and one to the auxiliary generator. Voltage transfer equipment is provided between these two main sources. If the power source feeding one of the busses fails, that source is disconnected automatically and the circuit breaker to the other source is closed automatically. At no time are the two sources of power paralleled because the air circuit breakers on the auxiliary system were not installed to handle simultaneously the short circuit kilovolt-amperes from both sources. In addition, the two sources may not be in phase and large circulating currents may be present if both are closed at the same time. During start-up of the station, both auxiliary busses, *1-A* and *1-B*, are supplied from the station service transformer. After the main unit is synchronized to the system, one of the auxiliary bus sections, usually *1-B*, is transferred by "open transition" to the auxiliary generator.

Test Objectives

The tests were to determine the optimum time interval between the opening of one circuit breaker and the closing of the other circuit breaker for a bus transfer. It is difficult to determine the optimum time interval except by actual test since an induction motor or a group of induction motors, when disconnected from their source, will continue to generate a voltage for some period of time. The period of time required for this voltage to decrease to substantially zero will vary depending upon the size, speed, and load on the motors. Figure 2 gives the typical open circuit time constants of typical motors. If the transition time is too short, the residual voltage on the motors which can be 180 degrees out of phase with the other source may cause excessive currents to flow in the motor windings when they are connected to the other source. (Squirrel-cage induction motors are designed to withstand mechanically a fully displaced locked rotor current from an infinite bus at the motor terminals.) If the transition time is long, other detrimental effects may be encountered in the station which will be discussed later.

Test records also were obtained on the operation of the automatic voltage regulator in the field circuit of the auxiliary generator when a bus was suddenly transferred to the generator. The recovery of the generator voltage depends on the action of the regulator which, in turn, is affected by the time for the various motors to come back to normal speed and power consumption.

Test Outline

The setup in the power plant is such that the speed at which a voltage transfer operation may be accomplished can be varied from a minimum of about 10 cycles up to several seconds. The longest transfer time is limited by the deceleration time of the circulating water pumps, whose discharge valves must be closed in the event voltage is removed for several seconds to prevent them from reversing. The circulating water pump may reverse if it is deenergized very long because the other circulating water pump will force water through the first one instead of through the condenser. To obtain test results for three time intervals, it was planned that transfers could be and would be made in about 10, 75, and 150 cycles.

It was desired to get as much informa-

Paper 50-59, recommended by the AIEE Power Generation Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30—February 3, 1950. Manuscript submitted March 21, 1949; made available for printing December 1, 1949.

A. A. Johnson is with the Westinghouse Electric Corporation, East Pittsburgh, Pa., and H. A. Thompson is with the Duquesne Light Company, Pittsburgh, Pa.

Figure 1. Schematic diagram of auxiliary system

Figure 2. Typical time constants for 2,300-volt squirrel-cage induction motors

A—3,600 rpm; *B*—1,800 rpm; *C*—600 rpm

tion as could be obtained on three oscillographs operating simultaneously. In addition to obtaining current to the large motors and the total bus current, power measurements were made for more complete information. The following simultaneous oscillograph records were obtained:

Currents	Power
Total to bus *1-B*	Total to bus *1-B*
Boiler feed pump	Boiler feed pump
Circulating water pump	Circulating water pump
Mill motor	**Voltages**
Forced draft motor	
Induced draft motor	Generator
Generator field	Bus *1-B*

The total current to bus *1-B* was obtained by paralleling the secondaries of the current transformers from the auxiliary generator and the service transformer so that when the bus was transferred, the current changed from one source to the other on the same record.

The first part of the tests covered four transfers of bus *1-B* from the generator to the transformer and back to the generator. During these tests the load on bus *1-A* was supplied from the transformer. Measurements were also made on tests involving three transfers of bus *1-B* from the transformer to the generator with bus *1-A* being supplied from the generator.

Bus 1-B Motors

The load on bus *1-B* of this auxiliary system during the tests consisted of about 2,500 kw made up of the 2,300-volt motors shown in Table I.

Test Results

Typical Oscillograms. Figure 3 is an oscillographic record of generator voltage, bus *1-B* voltage, total current, and total power before, during and after an 11-cycle transfer from the transformer to the generator. The generator field current also is shown. It will be noted from this record that bus *1-B* voltage decreased during the time the source was disconnected. At the instant of closing the circuit breaker to the generator, the first half cycle of total bus current is more than double the maximum half cycle of the current which follows. This is due apparently to a readjustment of flux conditions in the motor, and after a few cycles the motors take the normal current for their speed and load conditions. Figure 3 also shows that the average field current to the generator about doubled in less than one cycle. Figure 4 is an oscillographic record of the current and power to the 1,250-horsepower boiler feed pump motor, and the

Figure 3. Oscillographic record for transfer interval of 11 cycles for total load on bus 1-B

Transfer from service transformer to auxiliary generator

500-horsepower circulating water pump motor for a similar transfer time. The boiler feed pump acts as a generator when the source is disconnected, and supplies power to other motors connected to the bus. The power record on these motors is not the true total power because the measurements were made using a line-to-line voltage and a single-phase current which lagged the voltage by 30 degrees plus the power factor angle. Figures 5 and 6 show the same results for a transfer time interval of about 75 cycles. For Figure 5 the generator was carrying bus *1-A* prior to picking up bus *1-B*. The boiler feed pump motor supplies power to the other motors until the residual voltage decreases to zero.

Maximum Rms Inrush Current. The points shown on Figure 7 are the values of rms current for the maximum half cycle to bus *1-B* plotted against the transfer time interval. The curve on this figure is a calculated curve based on the total maximum half cycle of rms inrush current for all of the motors on bus *1-B*. This curve includes the effect of residual voltage on the bus and the impedances of the generator source. It was assumed that the residual voltage on the bus was 180 degrees out of phase with the source to which it was connected. All of the total measured currents were less than the calculated currents. The calculated currents, however, include full displacement of the rms current wave. Since the current was measured on only one phase for each test, the probability of obtaining a fully displaced wave was greatly reduced, but most of the current values are within a ratio of 1.6 or less of the calculated curve.

The inrush currents to the 1,250-horsepower boiler feed pump are shown in Figure 8. The points represent measured values, and the solid curve was calculated in a manner similar to that for the total current. The dashed line shows the maximum inrush current which the motor is designed to withstand mechanically. Thus it is clear that the time interval for safety to the bracings in the motor windings should be a minimum of about 50 cycles. Similar results were obtained for the other four motors on which measurements were taken. The results also apply to all motors on the auxiliary bus.

Residual Voltage on Motors. The residual voltage on this group of motors versus time is shown in Figure 9. This record incorporates the effects of the "open transition" time constants of the various motors as well as the decrease in speed due to motor loads. The residual voltage plotted against time was very similar for the various tests and reaches substantially zero in about 60 cycles.

The time required for the residual voltage on the bus to reach a phase position of 180 degrees with respect to the source voltage was 12 to 13 cycles. Thus a transfer time interval of 12 to 13 cycles would cause maximum inrush current to the motors. In about 20 cycles of open time the residual voltage would be back in phase after one slip cycle with the source voltage. In one test with a time interval of about 22 cycles, the maximum inrush current to the motors was materially reduced.

Time to Regain Normalcy. The time for the various motors to regain normal operation after being reconnected to a source is shown in Figure 10. This time is plotted against the open time interval. The curves show the relative order in which the motors are restored to normal operating conditions. The 1,250-horsepower boiler feed pump motor takes the longest time, and the fan motors take the least due to the torque limiting action of the magnetic coupler control.

The fan motors are connected to the fans through magnetic couplers. The

Table I

Motors	No. Units	Motor, Horsepower	Per Unit Pull Out Torque	Synchronous Speed
Boiler Feed Pump	1	1,250	2.38	3,600

Pulverizer exhausters	4	75		1,200
Circulating water pump	1	500	3.14	450
Hotwell pump	1	125		1,200

Figure 4. Oscillographic record for transfer interval of 11 cycles for boiler feed pump motor and circulating water pump motor

Figure 5. Oscillographic record for transfer interval of 75 cycles for total load on bus 1-B

Transfer from service transformer to auxiliary generator

field current to the couplers is taken from the supply to the fan motor through an electronic rectifier. The control on the rectifier is such that when full-load motor current is exceeded the field current is reduced and slip in the magnetic coupler increases. Thus with this type of control the fan motors will accelerate quickly after a transfer because the motor is essentially unloaded.

Voltage Disturbances. The greatest dip in voltage occurred for the fastest transfers. The generator voltage dropped to about 65 per cent of normal following an open time interval of 11 cycles, but recovered in about 60 cycles total time. For a time interval of 75 cycles, the generator voltage dropped to about 75 per cent of normal, but required a much longer total time of about 200 cycles to recover. For longer time intervals the voltage still dropped to about 75 per cent of normal, but took even longer to regain normal operation. These times may be obtained approximately from Figure 10 referred to above by adding the open time interval to the additional time required to reach normal conditions.

Auxiliary Generator Voltage Regulator. The generator voltage regulator operated satisfactorily for every test. The time for the regulator to take action was less than one cycle as shown on the oscillographic records given in Figures 3 and 5. In each case when bus *1-B*, which has a load of about 2,500 kw, was transferred to generator, the average field current increased about 100 per cent and stayed at a high value until the voltage on the generator terminals regained its normal operating value.

Boiler Operation. In every transfer test, up to a time interval of 150 cycles, the coal pulverizer mill motors and fan motors obviously decreased in speed; however, this decrease in speed had no noticeable effect on the fires in the boilers, nor was there any evidence of unsatisfactory operation of the boilers. The pulverizer mills were the ball mill Hardinge type and gave no evidence of stalling or unnecessarily increasing the duty on the motor when it was connected to the new source.

General Discussion

Tests which were limited to a maximum of 150 cycles had satisfactory motor transfers except that the circulating water pump was lost on one test. One period of time developed to be about 300 cycles, and many of the auxiliary motors were shut down by protective relays. Without question, this time of transfer is entirely too long, and in fact 150 cycles also is entirely too long. The preferred time interval should be when the residual voltage approaches zero, or for this system about 50 cycles.

During the transfer tests the station lighting and the 440-volt power equipment were connected to another source so they would not be affected. The control room fluorescent lighting was placed on another source because if the voltage is removed, the lights will go out and require several seconds to relight. The flickering of these lights on return of voltage would have been disturbing during the test periods. Under normal operating conditions this factor may not loom large in the over-all considerations of how auxiliaries should be transferred, but should be considered and additional lighting made available from some other source.

With the generator supplying bus *1-A* and transferring bus *1-B* to the generator, the voltage regulator performance also was very satisfactory. In fact, the results were similar to the first group of tests in which the generator was carrying no load prior to picking up bus *1-B*. The inrush currents to the motors also were approximately the same whether the generator was operating with or without bus *1-A*.

In practically every transfer test the first half cycle of inrush current to the motors was the largest. After this first half cycle, the current in most cases decreased sharply and then gradually increased for several cycles to a value corresponding to normal current for motor acceleration from the speed at which it happened to be at that instant.

Conclusions

1. For this auxiliary system the optimum transfer time interval is about 50 cycles. This transfer time assures greater mechanical safety to the motor windings than if a shorter transfer interval were used.

2. For transfers made in approximately 10 to 15 cycles, abnormally high motor currents may flow. This is caused by the fact that the residual voltage on the bus is still about 75 per cent of normal and is about 180 degrees out of phase with the new source voltage. This condition may cause a current considerably in excess of that for which the motor was designed mechanically.

3. The transfer of auxiliary bus sections by "open transition" can be safely accomplished. For any auxiliary system the preferred open time interval is determined by the time required for the residual voltage to decay to approximately zero. The actual time should correspond to no less than that which gives an inrush current to the motors equal to or less than the fully offset current which each motor would take when starting across the line from an infinite source at its terminals.

4. Automatic "open transition" transfers should be controlled by devices which give an accurate fixed open time interval. Such a device would insure that the inrush currents were not excessive, and also that the reclosing would not be delayed unnecessarily.

5. After the residual voltage has decreased to zero, the maximum inrush current to each motor is substantially the same for any time interval. The longer the open time interval, however, the longer it takes the motors to accelerate back to normal operating speed.

6. Delaying the transfers to the required 50 cycles will probably extinguish fluorescent lighting, but emergency lighting should assure that no area will be in darkness. The fluorescent lighting reestablishes itself when the bus is connected to the new source, but the flicker may be somewhat disturbing.

7. During the time residual voltage exists on the bus, the boiler feed pump motor supplies power to other motors. This has the effect of reducing the residual voltage faster. Other motors also may serve as generators during the time residual voltage exists if they have enough stored energy in the rotating parts.

8. When the load is transferred to the auxiliary generator, the voltage regulator must function to limit the voltage drop and to restore the voltage to normal.

9. The coal pulverizers operated satisfactorily for all transfer time intervals up to 150 cycles.

10. For all tests of 150 cycles or less, there was no noticeable effect on the normal operation of the station boilers.

Discussion

A. G. Mellor and **M. Temoshok** (General Electric Company, Schenectady, N. Y.): Although the open-circuit time constants for a group of induction motors are known individually, their effective time constant as a group connected together on a bus can be determined expediently only by test. In the present case the effective time constant of the bus was about one-half second although individual units may have had open-circuit time constants up to two seconds. This factor indicates a conclusion that should be emphasized: when a group of auxiliaries is transferred, the duty on each motor will be less severe than the duty on a single unit being transferred. Some station auxiliary motors can have time constants approaching four seconds, and to throw over single auxiliaries having this value of time constant, or even one appreciably smaller, alone or in combination with only a very few other auxiliaries would need re-evaluation of the time for the bus voltage to decay.

It should be noted that the transfer time of 50 cycles mentioned by the authors is the time for a planned transfer from an auxiliary bus at unit voltage to another bus at unit voltage. For this type of planned transfer, the time given by the authors approximates that which would be recommended for most auxiliary bus arrangements.

An auxiliary power system using a separate house generator which is not paral-

leled with the station service transformer requires that station auxiliary motors be transferred from the system to the house generator each time the station is started up or shut down.

A more common type of auxiliary power system uses a station service transformer connected to the main generator terminals and a starting transformer connected to the system. In this case, the auxiliary motors are started on the supply from the system and, after the main generator is up to speed, the transformer that is connected to the generator terminals is temporarily paralleled with the starting transformer. The starting transformer then is disconnected. This is what can be called a synchronized transfer during which the auxiliaries are never de-energized. With this system the only time motors are de-energized during transfer is in the case of an emergency transfer. In general, an emergency transfer would be made either because of loss of voltage on the auxiliary bus or because of a short circuit in the equipment supplying power to the auxiliary bus.

For the loss-of-voltage case, the voltage on the auxiliary bus would be reduced before transfer was actually started, and so the bus residual voltage would decay to a low value in a very few cycles after the start of transfer. For the extreme case of a 3-phase short circuit in the auxiliary power source, the motors on the auxiliary bus may feed into the short circuit, and the equivalent time constant of the bus would approach the short-circuit time constants of the motors, a matter of a few cycles. However, most emergency transfers will be made under circumstances less severe than this extreme case, and thus in some cases the reduction in residual flux of the induction motors may be approximately that shown in the paper.

Under emergency conditions, such as a fault on the auxiliary power source, it is often desirable to transfer the auxiliaries as rapidly as possible. Since motors are capable of standing, on an occasional emergency basis, the currents associated with rapid transfers, and since many operators have had years of successful experience with immediate transfers, it is recommended that all emergency transfers be made as rapidly as possible.

John G. Noest (Consolidated Edison Company of New York, Inc., New York, N. Y.): For the supply of generating station auxiliary power, it has been for a long time common practice to provide at least two sources of supply with switching arrangements to permit the choice of either.

In some of these cases it has been found either expedient or necessary to prevent parallel operation of the two supplies. In such cases, provisions must be made for the transfer of the load from one source to the other without intermediate paralleling. It is this latter type of arrangement which is treated by the paper.

Although such transfer schemes have been used for many years, there have been no reports of difficulties until just recently. The subject was first brought to the attention of the industry by Mr. E. H. Snyder of the Public Service Electric and Gas Company of New Jersey at the February 1948 meeting of the Edison Electric Institute at Cincinnati, Ohio.

The current paper by Mr. Johnson and Mr. Thompson furnishes quantitative data which should prove to be of considerable value to anyone confronted with a similar problem.

In connection with the paper, there arises one big question: Why is it that there have been no difficulties with bus transfer schemes throughout the many years that such schemes have been in use?

The answer to this question seems to lie in circuit breaker development. Where older circuit breakers had closing times of 30 to 40 cycles, with opening times of 8 to 12 cycles, a bus transfer scheme, without the provision of definite time delay, required 50 to 60 cycles in any case. Modern circuit breakers, with mechanisms designed for rapid reclosing, are so much faster that without definite time delay the transfer operation might take only as little as 20 cycles, and therefore the problem.

Another point of interest is brought out in this paper. It is the observation that boiler operation was unaffected with transfer times even up to 150 cycles. With pulverized-fuel-fired boilers there has been some apprehension on this point.

R. L. Webb (Consolidated Edison Company of New York, Inc., New York, N. Y.): We are much interested in the test results presented by Mr. Johnson and Mr. Thompson in their paper concerning transfer of station auxiliary motor load from one supply source to another. This subject received considerable attention in the Edison Electric Institute about two years ago. At that time some oscillograph tests were made in our Hudson Avenue Station on a system similar to that described in the paper.

In our case, six main auxiliary motors are connected to a single 2300-volt bus which is switched to a house service supply transformer, while the generator is being started. After the machine is synchronized to the main bus, the auxiliary bus is automatically transferred from the house service transformer to a 2,300-volt tertiary winding of the main generator autotransformer.

This 2,300-volt bus supplies two 600-horsepower 1,200-rpm induced-draft fan motors, two 250-horsepower 900-rpm forced-draft fan motors, one 450-horsepower 300-rpm circulating water pump motor, and one 75-horsepower 720-rpm Hotwell pump motor, or a total of 2,225 horsepower.

The transfer time, from the opening of one supply circuit breaker to the closing of the other, is about 45 cycles. This time is consumed by the operating time of the transfer relays plus the time taken by the incoming circuit breaker to close.

Figure 1 of the discussion shows two oscillograph records; the upper shows the current wave for all the motors combined, while the lower record is that of one 600-horsepower induced-draft fan motor alone.

Following the tripping of the supply circuit breaker, the motor bus voltage decreases with a time constant of approximately 23 cycles to 33 per cent of normal when the incoming circuit breaker was closed. During the 45-cycle period, the motors lost $1^1/_4$ cycle, indicating a speed drop of approximately 3 per cent. It will be noted that the motor voltage is approximately 180 degrees out of phase with the supply voltage after about 25 cycles. At the time the incoming circuit breaker was closed, the motor voltage was leading the supply voltage by approximately 90 degrees.

The lower record shows the motor load current to be 90 amperes before the first supply circuit breaker was opened. After tripping, it dropped to 46 amperes but reversed approximately 180 degrees, which indicates the motor was supplying power toward the bus without much change in the current value, for approximately 30 cycles. When the incoming circuit breaker was closed, the inrush current to the motor was less than 45 per cent of the normal starting inrush for this unit.

These records indicate no undue stresses are being imposed on these motors when they are transferred from the one source of supply to the other. The inrush current would be at about the minimum, if the transfer were made when the motor and supply voltages are exactly in phase with each other, which would have been about eight cycles earlier. However, it is not felt justified to make any changes in the control to gain this small advantage.

In 90 cycles after the load was transferred, the total motor running current was normal.

J. A. Elzi and **W. R. Brownlee** (Commonwealth Services, Inc., Jackson, Mich.): The tests described in this paper apply to one type of auxiliary power system, namely, one which is supplied from a shaft generator and a station service transformer. Much of

the test data is applicable to other types of auxiliary power systems and provides much useful information for the design and operation of such systems. It may be well to point out, however, that the method of transition and the conditions found to be optimum for this installation may not be found to be so for other systems. As the authors point out, even for a similar system the optimum conditions may be different depending on the number, speed, and size of the motors and the type of loads.

For this installation, open transition was used in order to avoid excessive duty on the circuit breakers and because of possible phase displacement. The circuit breaker duty could, of course, be taken care of by several methods, but the phase displacement might dictate open transition where an auxiliary generator is used. In station auxiliary systems supplied entirely from suitable transformers without the use of an auxiliary generator, the phase and voltage relations have been found to be such as to permit closed transition for normal operation, even for the most unfavorable conditions. This does not preclude the use of open transition during emergencies.

The system described by the authors uses a shaft house generator which avoids certain voltage dips, but it appears from the test data that the control may still be subject to such dips. Tests were reported in 1945 on a system using transformers to supply auxiliaries[1] where co-ordination of motor and control characteristics made operation immune to total interruptions as long as five seconds (compared with 150 cycles reported by the authors). Subsequent tests showed that this transformer supply system can operate on a sustained voltage reduction for several minutes down to 60-per cent voltage although the reduction in voltage due to open-circuit transition is only in the order of 10 per cent. This system affords substantial investment savings and improved reliability.

We disagree with conclusions 3 and 4 of the paper that the residual voltage must go to zero and that a fixed time interval is required for automatic open transition. Such an arrangement seems undesirable from a reliability standpoint, and appears to be unnecessary. For example, prevention of flame extinction with certain types of coal-pulverizer mills may require transfer time as short as 20 to 30 cycles.

Standard motors of some manufacturers will withstand such duty and if designs now contemplated do not allow for such operation, then these designs should be reviewed. This duty is very similar to that experienced with usual industrial applications where standard a-c contactors open and reclose motor circuits on external voltage dips lasting 10 to 30 cycles. Ordinary compensator starting provides a similar open interval using motors that may not have been braced for full voltage starting; also instantaneous reclosing on feeders supplying industrial loads is becoming the rule rather than the exception.

It is noted that high currents associated with short-time transfer are confined to one-half cycle. This would be expected and is consistent with other tests. We would like to ask the authors whether they feel that a one-half cycle current followed by normal starting current is likely to produce the mechanical stress expected with an offset wave having gradually decreasing peaks. It is recognized that the maximum station bus stresses are experienced a few cycles after the occurrence of a short circuit. It may be that the inertia of the motor conductors provides added margin for high currents during the first half-cycle.

Reference

1. Electric Drives for Steam-Electric Generating-Station Auxiliaries, W. R. Brownlee, J. A. Elzi. *AIEE Transactions*, volume 64, 1945, pages 741–45.

D. W. Taylor (Public Service Electric and Gas Company, Newark, N. J.): We have four 100,000-kw units in operation using practically the same throwover scheme of auxiliaries described in the paper by Mr. Johnson and Mr. Thompson. All essential auxiliaries, including a motor-driven exciter set, are thrown over to the shaft-end auxiliary generator shortly after synchronizing the main generator and are operated from that source until the unit is taken off the line. Only non-essential auxiliaries are normally operated from the station transformers. The automatic throwover therefore is needed only in one direction, from the auxiliary generator to the transformer feed. Two induction-type undervoltage relays are used to inaugurate the throwover on loss or lowering of the auxiliary generator voltage, one set for 70 per cent voltage and 12 seconds, to allow for a several-second dip in voltage occasioned by the starting of the 2,000-horsepower feedwater pump motors, and the other set for 50 per cent voltage, one-half second, to catch a more abrupt decline in voltage.

Tests we have conducted check well the results given in the paper. We find, however, quite a difference in time in the decay of the residual voltage, depending on the motors in service. Times from 50 to 100 or more cycles have been recorded. For this reason we use, instead of a fixed time delay, an undervoltage relay on each bus that delays the closing of the incoming circuit breaker until the residual voltage is reduced to about 20 to 25 per cent of the normal 2,400 volts. The closing time of the circuit breaker being added results in re-energizing the motors at about 400 volts residual. Inrush current can only be slightly greater than locked-rotor current, and tests show it is generally less. The fact that our boilers can be fired by either coal or oil, and some by gas, varies the motor load, as the mills and exhausters reduce the time of decay of the residual voltage. Thus it is possible to obtain a variation of the time to reach zero voltage on a given unit depending on the operating setup. We have found that the residual voltage slips 180 degrees out of phase in about 17 cycles with a decrement to zero of 70-80 cycles.

The operation of the four units now in service has been entirely satisfactory, and in several instances the automatic throwover has been tested by tripping the undervoltage relay and transferring the auxiliary load of 5,500 kw to 6,200 kw, including the motor-driven exciter set, with the main generator carrying from 80,000 to 100,000 kw.

F. W. Gay (Public Service Electric and Gas Company, Newark, N. J.): Figure 2 (A) of the discussion shows the voltage decay of number 14 bus at Burlington Generating Station. The voltage decays substantially to zero in about 50 cycles. This curve conforms very closely to the curve shown in Mr. Johnson's and Mr. Thompson's paper. The speed decays to approximately 90 per cent in 40 cycles.

Figure 2(B) of the discussion shows the voltage decay on bus Number 13 on Number 1 generator at Essex Generating Station. The two oscillograms are reduced so they show the same number of cycles per inch; therefore, the time of deceleration is propor-

tional to the physical length of the curves as shown on the two films.

In Figure 2(B) all of the auxiliaries connected with Number 1 generator at Essex Generating Station (100 megawatts) were thrown from the auxiliary power generator to the auxiliary power transformer simultaneously with the main unit carrying 85 megawatts; that is, the undervoltage relay that controls the automatic throwover was tripped. The curve shows that one of these circuit breakers delayed three or four cycles in opening, and it is believed that this was the Number 13 bus circuit breaker. Trace A, Figure 2(B) indicates the transformer current and shows the current taken by the transformer as the several busses were switched on. It appears that the Number 11 bus and the exciter switched on at approximately the same time. The Number 12 bus followed and the Number 13 bus was the last.

Trace *B*, Figure 2(B), gives the voltage on Number 13 bus. A study of this curve shows that the bus was de-energized for a little over 100 cycles. The speed fell to approximately 80 per cent and the voltage decayed to approximately 15 per cent in approximately 80 cycles. The break in the curve represents 230 cycles.

The transformer voltage as shown by Trace *C*, Figure 2(B), indicates approximately 1,220 volts at the time Number 13 bus was switched to the transformer; therefore, the transformer service voltage dropped from 2,400 to nearly 1,200 with a sustained current corresponding to a load at full voltage of approximately 20,000 kva. The large drop in voltage was produced by the transformer reactance and the protective reactors in the primary feed to the transformer.

Figure 3 of the discussion shows percentage voltage as ordinate and frequency as abscissa. Curve *A* shows the percentage voltage-time curve for the Burlington test; Curve *B* shows the percentage voltage-time curve for the Essex test shown in Figure 2; and Curve *C* shows the percentage voltage-time curve for a 500-horsepower motor driving the generator exciter.

It will be seen that it is rather dangerous to switch busses on the basis of time only when these curves show that there may be so great a discrepancy between the voltage decay curves under different conditions.

The designers of large motors tell us that large motors designed for across-the-line starting should not be re-energized until their residual voltage has fallen to about 20 per cent of normal. Accordingly we have equipped all busses with relays set to throw-over at approximately 500 volts. Since there is a time delay in the relay operation and circuit breaker closing, the actual voltages at the instant of re-energizing are considerably less than the 20 per cent specified by the designers. The 500-horsepower motor, Curve *C*, Figure 3, is designed especially for high-current starting, and the relays on this motor are set to throw-over at approximately 50 per cent residual voltage; but time delay due to circuit breaker closing, and so forth, after this voltage is reached gives a considerably lower voltage upon closing.

The tests on the 500-horsepower exciter motor were made at no load, and the speed during the 300 cycles diminished about one per cent.

A similar test was made on the same exciter at the Sewaren Station with a loaded generator and 850 amperes, or about 85 per cent of full-load field current, on the machine. At the end of 230 cycles after the opening of the circuit breaker the residual voltage was about 11 per cent and the speed about 77 per cent. The re-energizing was at 284 cycles, and the field current during this period fell from 850 to 600 amperes. The voltage regulator on this machine was cut out of service for this test.

A. A. Johnson and H. A. Thompson: The discussions by Mr. Taylor and Mr. Gay have added additional information on this problem which is very valuable. Their information adds appreciably to that which is contained in our paper. We agree that each auxiliary bus should be studied, or preferably tested, to determine its performance with respect to the residual voltage on motors. The use of an undervoltage relay, as employed by Mr. Taylor and Mr. Gay to delay the closing of the incoming circuit breaker until the residual voltage is reduced to about 20 to 25 per cent, is one way of insuring that the inrush current, when the auxiliary bus is reclosed, is limited. This method, however, in certain cases with motors or busses having long-time constants, may have to have the undervoltage relay set at a somewhat higher value than 20 per cent of rated voltage. In other words, this would be a compromise in order to protect critical loads in some applications. Consideration should be given in each case to the supply impedance in order to determine the inrush current to the motors when a bus is re-energized. The inrush current should be limited to a value equal to or less than the inrush current to each of the motors if they were started from an infinite bus at their terminals.

Mr. Brownlee and Mr. Elzi, in their discussion, point out that system tests have been made before and that interruptions having a time of five seconds could be tolerated. The 150 cycles or 2.5 seconds recommended in the paper was to some extent an arbitrary time because it was felt that this was very adequate even for making a test on the particular auxiliary system involved. We can see no reason for delaying the reclosure of the circuit breakers on to a new bus any longer than it takes for the residual voltage to decrease below the point where the inrush current to the motor will be limited. In connection with conclusions 3 and 4 of the paper, the only point involved here is that we are convinced that the motors should have the inrush current limited in order to be sure that they will give a satisfactory life. Whether this is done by a fixed time interval or by the use of an undervoltage relay as mentioned by Mr. Taylor and Mr. Gay seems immaterial as long as the motors are protected. Mr. Brownlee and Mr. Elzi also point out that to prevent flame extinction with certain types of coal-pulverizer mills requires transfer time as short as 20 to 30 cycles. The authors are not acquainted with any situation where such a short interval of time is necessary. Actually, we have no test results on this point except in a test where the Hardinge Mills were used, and there was apparently no effect on the flames for the time intervals used during this test. We have heard, however, of other abbreviated tests where the flame extinction was an important point when the time interval was about a minute or more.

Mr. Brownlee and Mr. Elzi also make the statement that standard motors should be capable of withstanding immediate reclosure when transferred by the open-transition method as discussed in the paper, and if the designs do not, then they should be reviewed. We do not know of any difficulties which have been experienced on motors from this cause, but it would appear that this is not necessarily a requirement of a standard motor and these special requirements should be discussed with the designer in advance of building such motors. It also was pointed out that reclosing on industrial feeders was frequently accomplished from 10 to 30 cycles and that industrial motors should be braced to withstand inrush currents from such service. It should be noted that the impedance in the feeder circuits will limit inrush currents to industrial motors to current values which are usually safe for the motors. Mr. Brown and Mr. Elzi mentioned that the inertia of the motor conductors on auxiliary systems may provide a margin of safety for the half-cycle of high-peak current. We have no specific data on this point, but we recognize that it well may be an important factor.

We appreciate the additional data provided by Mr. Webb in his discussion. In connection with transfering his group of motors eight cycles earlier in order for the two voltages to be in phase, it is quite likely that the variable load on the motors will cause the optimum time point to vary over a range of a number of cycles. It would appear that with the voltage reduced to the value shown in Figure 1 of the discussion the motor when re-energized will have the current limited to a safe value. Again the system reactance will help accomplish this.

Mr. Noest raised the question as to why it is that there have been no difficulties with bus-transfer schemes throughout the many years that such schemes have been in use, and very ably offered the answer. Most transfers in the past have had open-time intervals of sufficient duration to allow the residual voltage on the motors to reduce to a point where upon being re-energized the maximum inrush current has been limited. However, in recent years with higher speed circuit breakers and relaying the time interval may have to be controlled by probably introducing longer delays than that inherently offered by the circuit breakers. This is a primary reason for making the tests presented in the paper.

The discussion by Mr. Mellor and Mr. Temoshok gives a further review of some of the factors involved in open transition. We agree that the duty on each motor when transferred as a group will be less severe than the duty on a single motor being transferred. On the basis of the results in the paper, however, we disagree that the transfer time of 50 cycles is the time for a planned transfer. It is a time interval which should be used for all transfers to provide maximum safety to the motor. As to the closed transition where the supply to the auxiliary busses is provided from transformers, we feel that there is a definite hazard if it is left up to the operator to disconnect one of the power sources after the transfer has been accomplished. In one

case on the Duquesne Light Company's system where two transformers were used, the operator forgot to disconnect one source and the circulating current, because of too large a phase angle between the two sources, caused the current transformers in the common connection to heat up and fail. If closed transition is used, there should be some automatic arrangement provided so that after a short time interval one of the sources is automatically disconnected. We know of several cases where the transfer from one bus to another was made because the voltage on one source was reduced below normal value and remained at this point for an appreciable time interval. Therefore, we feel that the open-time interval should be either a fixed quantity which has been determined to be safe, or undervoltage relays which measure the residual voltage should dictate when the motors are closed in on the good source. There are too many possible combinations of situations which may arise to try to differentiate between when a source has a short circuit and when the voltage is reduced for some other reason. If it is safe to transfer on a planned basis with a time delay of, say, 50 cycles as in this case, then we feel that it is also safe to transfer in this time for any of the situations which might occur.

We appreciate the comments and the contributions given in the discussions. We would like to re-emphasize the point which has been made that there have been many auxiliary busses transferred on the open-transfer basis, but that inherently most of these have had time delays ranging from 30 to 60 cycles, depending upon the relay and circuit breaker times. With the more modern circuit breakers and relays operating at much faster times, this question of time interval assumes more importance, and we think should be given consideration when this scheme is used. The scheme has a very definite advantage in that the two sources are not paralleled, and, therefore, troubles from this are not in evidence. In addition lower short-circuit kilovolt-ampere circuit breakers can be used because on the closed transition, in order to protect for possible short circuits during the closed time interval, either higher short-circuit kilovolt-ampere circuit breakers are required, or current-limiting devices such as series reactors must be provided. In any event, if the closed transition scheme is used, some measure of limiting the short-circuit current should be built into the system.

As a matter of interest, the test results given in the paper were obtained in November 1948.

Regulation of A-C Generators with Suddenly Applied Loads—Part II

E. L. HARDER
FELLOW AIEE

R. C. CHEEK
MEMBER AIEE

J. M. CLAYTON
ASSOCIATE AIEE

THE determination of the voltage regulation of a-c generators with suddenly applied load has become a problem of considerable importance. When the load which may be added suddenly is appreciable compared with the connected generating capacity, consideration must be given to the effect of the voltage drop on other connected load as well as on that just added. Too great a drop may result in the dropping out of a-c contactors on other equipment, stalling of heavily loaded motors, malfunctioning of radar or other voltage-sensitive equipment, and in adverse effects upon the starting characteristics of motors thrown on the line. Relatively small power plants with large motor loads are particularly subject to this phenomenon since the starting load may be several times the running load. Examples are isolated coast-defense gun installations, naval ship-service generators, industrial power plants, and the auxiliary house generators of central-station power plants. In the latter case a heavy auxiliary motor load may be transferred suddenly to the house generator in the event the normal supply fails.

In a previous paper[1] the case of generators with self-excited exciters was treated. Curves were given showing the maximum voltage drop as a function of the added load, the exciter response, and the generator reactance and time constant. The exciter responses covered were 0.5, 1.0, and 3.0. Later problems arose making it desirable to extend the data to include response of 10.0 in order to permit interpolation for responses above 3.0 in special cases. The resulting curves are presented here without further explanation since their basis is thoroughly discussed in the earlier paper.

This paper deals primarily with generators having separately-excited exciters, Figure 1. This arrangement is used primarily for large central-station generators where the voltage-drop problem occurs less frequently, but also applies to house generators and to generators in large industrial plants, where voltage drop is of prime importance.

However, the curves presented are the mathematical solution of a basic regulating system whose performance may be expressed as follows: At time zero, Figure 2, a load, or an additional load, suddenly is thrown on the generator, causing a sudden drop in terminal voltage. A definite time, h, later a direct voltage, is suddenly impressed in the exciter field circuit and starts to build up the exciter field current. In the indirect-acting regulator this is accomplished by closure of the quick response contactor, Q, Figure 1. As the exciter builds up, the downward trend of generator voltage is halted at some time, t, and the voltage is started upward toward normal. Thus any regulating system which can be interpreted as impressing the same fixed voltage into the exciter field circuit a definite time, h, after the disturbance, can be treated by this data. It is the solution for a basic regulating system, taking into account exciter and generator characteristics.

The voltage-drop curves are presented with a statement of the basic assumptions, some examples of application and supplementary information for estimating machine constants when accurate design values are not known.

The theoretical analysis is given next, including the conversions to and from the electrical analog used on the Anacom.[2,3] All of the basic computations were carried out on the Anacom, an electric analog computer. An analytical solution, corresponding to that given in the previous paper,[1] is included for use with specific problems where the Anacom is not available.

Voltage-Drop Curves for A-C Generators with Separately-Excited Exciters

The voltage-drop curves for generators with separately-excited exciters are given in Figure 3. There are 12 graphs in all, covering four values of exciter response, R, from top to bottom, and three values of generator open-circuit time constant, T_{do}', from left to right. Each graph is a family of five curves for different values of generator transient reactance, x_d'. The maximum voltage drop is plotted as ordinate against the suddenly-applied load as abscissa. The applied load is treated as a fixed impedance of low power factor and is expressed, not as the current actually drawn, but in terms of that which would have been drawn with maintained voltage. This current is expressed in per cent of generator rating.

Example 1: The simplest problem is a direct one. Determine the voltage drop that would be caused by a 300-horsepower induction motor starting at reduced voltage of 60 per cent through a starting transformer on a 2,000-kva generator having an open-circuit time constant, T_{do}', of 3.0 second, and a transient reactance, x_d', of 20 per cent. R is 1.0, and an indirect-acting regulator with quick response contactors is used. The full-voltage starting current of the motor is given as 6.5 times normal and the rated kilovolt-amperes as 280.

Paper 50-58, recommended by the AIEE Power Generation, and Transmission and Distribution Committees and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted November 1, 1949; made available for printing December 1, 1949.

E. L. Harder, R. C. Cheek, and J. M. Clayton are all with the Westinghouse Electric Corporation, East Pittsburgh, Pa.

The derivations of Appendixes II and III were taken from a thesis, "Suddenly-Applied Loads on Generators with Quick-Response Excitation," by R. C. Cheek, submitted to the University of Pittsburgh in partial fulfillment of the requirements for the degree of Master of Science, June 1943.

Figure 1. Essential components of excitation system with indirect-acting regulator and separately-excited exciter

Figure 2. Terminal voltage versus time after a sudden load application

At the reduced voltage (assumed maintained) the motor inrush in per cent of generator rating would be

$$\text{Applied load} = \frac{280 \times 6.5 \times (0.60)^2}{2{,}000}$$

$$= \frac{656}{2{,}000} = 32.8 \text{ per cent}$$

In Figure 3, curves are available for a response of 1.0 but it will be necessary to interpolate between $T_{do}' = 2$ and 4. For $R = 1.0$, $T_{do}' = 2.0$, the voltage drop at 32.8 per cent load is 6.5 per cent as read on the curve for $x_d' = 20$ per cent. For $R = 1.0$ and $T_{do}' = 4.0$, the drop at 32.8 per cent load is 6.4 per cent. These values are the same within the accuracy of the curves. The voltage drop may be taken as 6.5 per cent.

Example 2: The indirect problem may occur in many forms. One might be to determine the size of the largest motor that can be started across the line on a 5,000-kva generator without exceeding 15 per cent drop under the following conditions:

Separately-excited exciter.

Indirect-acting regulator with quick-response contacts.

Generator open-circuit time constant, $T_{do}' = 2.0$ seconds.

Generator transient reactance, $x_d' = 20$ per cent.

Exciter response, $R = 0.5$.

Ratio, motor kilovolt-ampere per horsepower $= 0.9$.

Motor starting current $= 6$ times normal.

From the curve of Figure 3 for $R = 0.5$, $T_{do}' = 2.0$, $x_d' = 20$ per cent, the applied load to result in 15 per cent drop is found to be 52 per cent. The starting inrush therefore may be 52 per cent of $5{,}000 = 2{,}600$ kva, or the motor kilovolt amperes may be $2{,}600/6 = 433$. The largest motor permissible with the specified conditions is $433/0.9 = 480$ horsepower.

Use of Curves with Other Regulating Systems

A certain amount of information regarding voltage drop with other types of regulators can also be derived from the curves of Figure 3. Any regulating system which has the same field-circuit time constant and impresses the same voltage in the same time will result in identical voltage drop for a given added load.

In particular, if the variable field-circuit resistance in the system treated were eliminated and a regulating system which inserted a voltage directly in the field circuit were used, the same drop would be obtained upon application of load if the regulator inserted the same voltage as that which previously appeared across the variable field-circuit resistance at no load.

For example, suppose an exciter has a certain nominal response and is designed to have 82 volts across the variable resistance when operating at no generator load. Also, suppose that the fixed resistance in the circuit, including the field and any external resistance not short circuited is 40 ohms. The voltage impressed by a different regulating system as a result of the voltage drop would have to be 82 volts and the resistance of the field circuit into which it was impressed would have to be 40 ohms in order for the curves of Figure 3 to apply. If the voltage were less or the field-circuit resistance more, the voltage drop would be increased, and vice-versa.

Factors Influencing Voltage Regulation

The maximum voltage drops have been given as functions of the four principal parameters; namely, added load, generator transient reactance, generator time constant, and exciter response. There are a number of other factors entering into the equations for maximum voltage drop, but as has been shown previously[1] these are generally minor factors which justifiably can be represented by average values in determining voltage drops.

All the various factors that affect the terminal voltage of a generator during the starting of a large motor or other load were discussed in detail in the previous paper. In this paper, only a brief statement adequate to define the conditions for these curves is given in regard to each factor.

Typical values of the principal factors affecting voltage drop are given in Table I and Figure 4. In the Table the value above the line represents the average of a large number of machines considered and the values below the line give the range. The values of all the minor parameters held constant in the study are given in Table II.

Generator Transient Reactance, x_d'

The curves of Figure 3 are plotted in terms of the saturated or rated-voltage value of transient reactance, x_d' saturated, which is the value customarily supplied by the manufacturer as the transient reactance, x_d', of the machine.

Generator Synchronous Reactance, x_d, and Short-Circuit Ratio

The maximum voltage drop increases with an increase in synchronous reactance. With average generator and exciter characteristics, the change in maximum drop at 100 per cent applied load is about two parts in 25 as x_d is varied from 120 per cent down to 100 per cent or up to 140 per cent. With 20 per cent saturation at no load, the corresponding variation in short-circuit ratio is from 1.0 up to 1.2 or down to 0.86. These variations from the average x_d of 120 per cent are as large as are usually encountered among normal machines, and the curves of Figure 3 can be used directly for normal machines without serious error for most purposes.

An accurate figure for maximum voltage drop may be required in some cases where generator synchronous reactance differs greatly from 120 per cent. The curves of Figure 3 can be used for the precise determination of drop in such cases by first expressing generator reactances and the applied load on a new kilovolt-ampere base, such that x_d on the new base is 120 per cent, and then applying the curves. For example, suppose a low power-factor load of 1,500 kva (expressed at full voltage) is to be applied to a 3,000-kva generator having 30 per cent transient reactance and 150 per cent synchronous reactance. Suppose that the generator time constant is 4.0 seconds and the exciter has a nominal response of 1.0. To determine the drop, express the transient reactance and the applied load on the kilovolt-ampere base upon which x_d is 120 per cent. The base in this case will be 3,000 by $120/150 = 2{,}400$ kva. On this base the transient reactance x_d' is 30 by $2{,}400/3{,}000 = 24$ per cent, and the applied

load is 1,500/2,400 = 62.5 per cent. From the curves of Figure 3, the maximum voltage drop is 13 per cent for 62.5 per cent load applied to a generator having 24 per cent transient reactance, a time constant of 4.0 seconds, and an exciter of 1.0 nominal response. This same maximum drop would be obtained with the machine and load under consideration.

Generator Open-Circuit Time Constant, T_{do}'

This time constant is the ratio of inductance to resistance of the generator field circuit under unsaturated conditions. The resistance should include all resistance in the field circuit. Typical values for the machine alone are given in Figure 4.

Generator Quadrature-Axis Synchronous Reactance, x_q, and Saturation, s

The drop is almost independent of x_q over the practical range of its variation, the value 0.75 being a good average. Curves are based on 20 per cent saturation ($s = 0.20$) although s can be varied from 0 to 0.4 without materially altering the drop.

Exciter Response, R

The exciter response, R, is the nominal response as defined by the American Standards Association. It is the average rate of open-circuit exciter voltage increase from nominal voltage during the first half-second after the field resistance is short-circuited, expressed in per unit of nominal voltage. Nominal voltage is understood to be that required on the slip rings when the generator is operated at rated voltage, load and power factor. It is necessary that the response, R, used in estimating voltage drop be based on cutting out the same resistance as is cut out by the quick-response contactors in the actual application.

Regulator Operating Time, h

The regulator operating time has been taken as three cycles or 0.05 second. The quick-response contactors of indirect-acting regulators are frequently guaranteed to operate within this time for a voltage drop of ten per cent or more. If the transient-reactance voltage drop is insufficient to operate the quick-response contacts, the regulator action is comparatively slow and the curves do not apply in this region.

Initial Load

The curves are based on no initial load but also apply if initial load is present. It has been shown that the effect of initial load is to cause somewhat less drop if the load is static, somewhat more drop if the load is dynamic (running motors), and about the same drop if the load is about evenly divided. Thus the no-load case also is representative of an average mixed initial load.

Characteristics of Applied Load

The curves of Figure 3 are based on a constant-impedance applied load, which can be used to represent an induction motor during the starting period. In the curves, the power factor of applied load was taken as 35 per cent, a typical motor-starting power factor. The maximum voltage drop is practically the same for all power factors from zero to 40 per cent but decreases rapidly for power factors above this.

Solution on the Anacom

Preparation of the curves of Figure 3 required maximum voltage-drop calculations for some 300 conditions (3 time constants by 4 exciter responses by 5 reactances by 5 applied loads), and so it was decided to use the Anacom for the actual computation. There were several main steps to the solution.

THEORY DEVELOPMENT

1. Derivation of equations describing the phenomena.

2. Conversion from exciter response, R, to an equivalent ceiling voltage, e_g, and time constant.

3. Development of an analog and determination of the analogous relations.

COMPUTATIONS

4. Computation of e_c and T_c.

5. Determination of initial conditions and conversion of data to analog.

6. Analog computations of e and conversion to e_d.

7. Machine or slide rule computation of e_t from e_d.

These various steps now will be discussed.

1. *Derivation of Equations of the System*

The necessary equations for use in the analog method of solution are described in Appendix I, directly or by reference. Equations 3, 3A, and 6 give conversions from e_d' to e_t, e_t to e_d, and T_{do}' to T_d', required in the computations. Equations 11A and B give the differential equation in two regions, first from the time that load is added at $t = 0$ until the regulator acts at $t = h$.

2. *Conversion from Exciter Response to Ceiling Voltage and Time Constant*

Appendix II is a derivation of the relationship between the exciter nominal re-

Table I. Typical Values of Principal Factors Affecting Voltage Drop*

	x_d	x_d' saturated

Figure 3. Voltage drop versus suddenly applied load for generators having separately-excited exciters and with various transient reactances, x_d', time constants, T_{do}', and nominal exciter responses, R

Figure 4. Typical open-circuit time constants of machines of different sizes and speeds

sponse and its ceiling voltage and time constant, the results being plotted graphically in Figure 6.

3. *Electrical Analog of Regulating System*

The circuit shown in Figure 5 is an electrical analog of the regulating system after the load has been added at $t=0$. This may be shown by comparing the differential equation for $(e+E_2)$ of Figure 5 with that for (e_d-1) of the actual generator. Note particularly that the analog does not give the initial transient-reactance drop, but only the variation of voltage after this drop has occurred. When S_2 is closed, the condition simulated is that of the actual system just *after* $t=0$. The analog gives, in effect, the variation of field current, which is proportional to e_d, from this instant on.

In Figure 5, S_2 closes at $t=0$ and E_2 starts to charge C_2 negatively. (This is equivalent to placing a positive charge on C_2 at $t=0$ and letting it discharge.) The circuit R_2C_2 has very high impedance compared with R_1C_1 so that the voltage of C_1 remains substantially zero during this interval. At $t=t_1=h$, the regulator-operating time, switch S_1 closes and E_1 starts to charge C_1 positively. The positive voltage of C_1 eventually rises so that the downward trend of e is halted and e starts upward. It may be noted that this action simulates that of the regulating system. Mathematically the performance of the circuit is expressed as follows, the equations being written by inspection from Figure 5.

If $0<t<t_1$

$$0=(e+E_2)(1+pT_2) \tag{1A}$$

If $t>t_1$

$$E\left(1-\epsilon^{-\frac{t-t_1}{T_1}}\right)=(e+E_2)(1+pT_2) \tag{1B}$$

E_2 is simply a convenient equivalent to an initial charge placed on C_2. Note that $pT_2E_2=0$. Equations 11A and B of the actual system from Appendix I are included here for reference.

If $0<t<h$

$$0=(e_d-1)(1+pT_d') \tag{11A}$$

If $t>h$

$$(e_c-1.2)\left(1-\epsilon^{-\frac{t-h}{T_e}}\right)=(e_d-1)(1+pT_d') \tag{11B}$$

Observe that equations 1A and B are identical to 11A and B provided that

$$e+E_2 \equiv e_d-1 \tag{2A}$$

$$T_2 \equiv T_d' \tag{2B}$$

$$t_1 \equiv h \tag{2C}$$

$$T_1 \equiv T_e \tag{2D}$$

$$E_1 \equiv e_c-1.2 \tag{2E}$$

Hence the circuit of Figure 5 is analogous to the regulating system, Figure 1. Suitable time-scale and voltage-magnitude transformations can be made to suit the requirements of the analog computer. The impedance base can be selected at will since it is not fixed by the analogous relations, equation 2.

4. *Determine e_c and T_e*

The exciter response, R, must be converted to an exciter time constant, T_e, and ceiling voltage, e_c. From Figure 6 it may be observed that the same response may be obtained with different ceiling voltages.

However, exciters with different ceilings and the same response produce about the same maximum voltage drop so that this solution is not critical. The ratios of ceiling to nominal voltages selected for the study all lie on the straight line drawn across the figure and vary from 1.5, for a response of 0.5, to 5.0 for a response of 10.0. These values all correspond to reasonable designs. Selection of ceiling to nominal voltage ratio fixes the time constant. Nominal exciter voltage was taken as 2.4 times that corresponding to rated voltage on the generator air-gap line. Thus ceiling voltage e_c is 2.4 times the ratio e_c/e_n given in Figure 6.

5. *Determine the Initial Value of e_d*

The direct-axis transient internal voltage, e_d', prior to $t=0$ can be calculated from equation 3, e_t being unity before load is added; e_d' is proportional to the flux linkages with the main field and does not change when the load is added. Thus it has the same value immediately after $t=0$. The initial value of e_d, after $t=0$, can be obtained from e_d' using equation 5. This provides the initial value of e_d and hence of the variable (e_d-1) used in equations 11A and B. Next determine T_d' from T_{do}' using equation 6. The parameters e_c, T_e, T_d', h, and the initial value of e_d now are known and can be converted to analog values, E_1, T_1, T_2, t_1, and E_2 respectively, using equation 2. Note here the convenience of the direct analog-computing method in that each parameter influences only one separately-adjustable parameter of the analog.

6. *Analog Computations of e and Conversion to e_d*

With the analog set at these or proportional values, the minimum value (greatest negative value) of e is read from the computer. Figure 7 shows the voltages E_1 and E_2 and a typical solution for e from the computer. It is of interest to note that the time as well as magnitude of the lowest voltage can be obtained using the computer although only the maximum drop was used in this study. Now having the most negative value of e, we have the minimum value of $e+E_2$, which is minimum (e_d-1), except for the voltage transformation selected from computer to system.

7. *Computation of e_t from e_d*

From the minimum value of e_d the minimum terminal voltage, e_t, is computed using equation 3A.

Thus the analog computer solves the differential equations of the system to determine the minimum e_d, whereas the computations represented by equations 3, 3A, 5, and 6 are done by slide rule or desk-calculating machine.

Voltage-Drop Curves for A-C Generators with Self-Excited Exciters

The regulating system studied previously,[1] for generators having self-excited exciters, is shown in Figure 8. The voltage-drop curves for this regulating system, which also have been published,[1] are included in this paper, Figure 9. Additional curves, not published before, are included for an exciter response of 10.0; voltage drops on systems having exciter

responses above 3.0 can be interpolated readily with these curves.

Analytical Solution for e_d' and Time of Maximum Drop

In the previous paper analytical expressions for e_d' and the time of maximum drop were derived for the case of self-excited exciters. A corresponding derivation is given in Appendix III for the separately-excited system. These expressions may be used in longhand calculations of specific problems where a computer such as the Anacom is not available. The voltage e_d' can be converted to e_t by use of equivalent relations given in Appendix I.

Verification of Voltage-Drop Curves

As the method of computation has been verified already[1] by experimental tests, it was only necessary in this case to spot check the 300 computer calculations. Seven strategically spaced points were checked by direct calculation from the formulas and all agreed with the computer results to well within ±1.0 per cent drop. This is within the expected computer accuracy.

Conclusions

As a result of the studies described in this paper and in reference 1, the following conclusions have been reached regarding the importance of various factors affecting voltage drop with suddenly applied low power-factor load:

1. The maximum voltage drop accompanying suddenly applied low power-factor load can be expressed in terms of four main parameters for generators with self-excited exciters and separately-excited exciters.

2. In the generator, the transient-reactance and the open circuit time constant are of prime importance. Reasonable variations in synchronous reactance have less effect. A method is presented for correcting for wide variations in synchronous reactance when using the voltage-drop curves; this method applies to generators with self-excited or separately-excited exciters. Variations in quadrature reactance and saturation have practically no effect on maximum voltage drops.

3. For self-excited and separately-excited exciters, the nominal response adequately expresses for practical cases the effect of exciter characteristics upon maximum voltage drops.

4. As has been shown before,[1] the regulator operating time, initial load, and variations in the power factor of the applied load from 0.0 to 40 per cent have negligible effect on the maximum voltage drop.

In general, greater voltage drops occur on generators having self-excited exciters with a given response than on generators having separately-excited exciters with the same response, assuming that all other factors affecting voltage drop are equal. For the range of parameters covered by the curves, the difference in the voltage drops for similar operating conditions may be as great as 14 per cent or may be less than 0.5 per cent depending upon the particular machine constants and applied load conditions. For a large number of cases the difference in the voltage drops for the two excitation systems will be within a range of 2 to 10 per cent. This gives some idea of the error involved if the voltage-drop curves presented in the previous paper are used to determine the voltage drop on generators with separately-excited exciters. Even though it is recognized that the voltage drop given by the previous curves is pessimistic for generators with separately-excited exciters, the magnitude of the error cannot be estimated readily, since it varies with machine and exciter constants and applied load conditions. Therefore, this separate treatment of systems with separately-excited exciters is considered necessary.

Appendix I. Equations for Terminal Voltage as a Function of Time for Generator with Separately-Excited Exciter and Suddenly Applied Load

As shown in Figure 1 for a sudden load which drops the terminal voltage enough to close the regulator quick-response contacts, a block of resistance is short-circuited in the exciter field circuit.

Neglecting subtransient effects, the generator terminal voltage suffers a sudden initial transient drop, followed by a gradual drop from transient toward the synchronous value. In the meantime regulator action raises the exciter voltage, halting further drop and restoring voltage to normal. As the voltage approaches normal, antihunt devices take effect, slowing the rise. However, these usually will have no effect on the minimum voltage reached during the dip.

If it is assumed that the build-up of exciter voltage follows an exponential law from its

initial to its final value when its field resistor is cut out, an analytical expression can be obtained for the terminal voltage at any time during the dip until the contacts are again opened due to antihunt action of the regulator.

Further assumptions are that the speed is constant, the initial and added loads are pure impedances, and generator saturation requires a fixed excitation, s, to overcome it.

The internal voltage of the machine back of transient reactance, namely e_d', is associated with the flux linkages which remain constant when the load is suddenly changed. The relationship[4] between terminal voltage e_t and internal voltage e_d', is at any instant, neglecting subtransient effects

$$e_t=\sqrt{\frac{(x_{qt}^2+r_t^2)(x_{wxt}^2+r_{wxt}^2)}{x_{dt}'x_{qt}+r_t^2}}\;e_d' \qquad (3)$$

Also

$$e_t=\sqrt{\frac{(x_{qt}^2+r_t^2)(x_{wxt}^2+r_{wxt}^2)}{x_{dt}x_{qt}+r_t^2}}\;e_d \qquad (3A)$$

as shown by equation 5 combined with equation 3.

Using the constant saturation concept, the fundamental field-circuit equation becomes

$$e_x-s=e_d+T_{do}'\,p\,e_d' \qquad (4)$$

The relationship between e_d and e_d' is given by Wagner[4] as

$$e_d=\frac{x_{dt}x_{qt}+r_t^2}{x_{dt}'x_{qt}+r_t^2}\;e_d' \qquad (5)$$

Also[4]

$$T_d'=\frac{x_d'x_{qt}+r_t^2}{x_{dt}x_{qt}+r_t^2}\;T_{do}' \qquad (6)$$

Substituting for e_d' and T_{do}' in equation 4

$$e_x-s=e_d+T_d'p\,e_d \qquad (7)$$

If $0<t<h$

$$e_x-s=e_{x1}-s \qquad (8A)$$

If $t>h$

$$e_x-s=e_{x1}-s+(e_c-e_{x1})\left(1-\epsilon^{-\frac{t-h}{T_e}}\right) \qquad (8B)$$

And since

$$e_d=(e_{x1}-s)+(e_d-e_{x1}+s) \qquad (9)$$

If $0<t<h$, then equation 7 becomes

$$0=(e_d-e_{x1}+s)+T_d'p(e_d-e_{x1}+s) \qquad (10A)$$

If $t>h$

$$(e_c-e_{x1})\left(1-\epsilon^{-\frac{t-h}{T_e}}\right)=(e_d-e_{x1}+s)+T_d'\times p(e_d-e_{x1}+s) \qquad (10B)$$

For the special case of no initial load

$$e_{x1}-s=1.0$$

and since s is to be taken as 0.20

$$e_{x1}=1.20$$

so that if $0<t<h$, equations 10A and B reduce to

$$0=(e_d-1)(1+pT_d') \qquad (11A)$$

If $t>h$

$$(e_c-1.20)\left(1-\epsilon^{-\frac{t-h}{T_e}}\right)=(e_d-1)(1+pT_d'). \qquad (11B)$$

Equations 11A and B are the desired differential equations for e_d, the direct-axis synchronous internal voltage; e_d is equal to the instantaneous field current in per unit. The equations 11A and B for e_d, and equation 3A, for the terminal voltage e_t in terms of e_d, constitute a complete mathematical expression for e_t as a function of time after the sudden load application at $t=0$.

Appendix II. Derivation of Curves of T_e as a Function of R, e_c, and e_n

From the definition of nominal response the shaded area under the curve in Figure 10 equals the shaded area under the straight line, the slope of which is Re_n. That is

$$\int_0^{0.5}\left[e_n+(e_c-e_n)\left(1-\epsilon^{-\frac{t}{T_e}}\right)\right]dt=\frac{Re_n}{8}+\frac{e_n}{2} \qquad (12)$$

or, integrating the expression on the left

$$T_e\left(\epsilon^{-\frac{1}{2T_e}}-1\right)+\frac{1}{2}=\frac{Re_n}{8(e_c-e_n)} \qquad (13)$$

Dividing equation 13 into unity, we get

$$\frac{1}{T_e\left(\epsilon^{-\frac{1}{2T_e}}-1\right)+\frac{1}{2}}=\frac{8}{R}\left(\frac{e_c}{e_n}-1\right) \qquad (14)$$

Equation 14 contains T_e as an implicit function of R and the ratio of e_c to e_n. Figure 6 is plotted from this relation.

Appendix III. Analytical Solution for e_d' for Generator with Separately-Excited Exciter

In the previous paper,[1] which treated only the case of generators with self-excited exciters, an analytical expression was derived for the volt-time curve of e_d' after sudden application of load. Although the Anacom was used in the actual calculations for the curves of Figure 3 of the present paper, a corresponding analytical solution for the case of separately-excited exciters will be useful for the calculation of special cases,

Figure 11. Exciter build-up curve, including delay caused by regulator operating time, h

where the Anacom is not available. For completeness, therefore, a similar analytical solution is included herewith for this case. The method of solution and the notation correspond to those of the previous paper.

Using the Heaviside unit function $H(t)$ and the delayed unit function $H(t-h)$, we can synthesize a mathematical expression for the exciter voltage as a function of time after load is applied. From Figure 11

$$e_x=e_{x1}H(t)+(e_c-e_{x1})\left(1-\epsilon^{-\frac{t-h}{T_e}}\right)H(t-H) \qquad (15)$$

The quantity h is the time delay in the regulator after load is applied. Substituting equation 15 into the field-circuit equation, equation 4 of Appendix I, and making use of equations 5 and 6 of Appendix I

$$\frac{de_d'}{dt}+\frac{1}{T_d'}e_d'=\frac{1}{T_{do}'}\left[e_{x1}H(t)+(e_c-e_{x1})\times\left(1-\epsilon^{-\frac{t-h}{T_e}}\right)H(t-h)-sH(t)\right] \qquad (16)$$

Writing equation 16 in operational form and adding $e_d'{}_1$, the initial value of e_d', we get

$$\left(p+\frac{1}{T_d'}\right)e_d'=\frac{1}{T_{do}'}\times\left[(e_{x1}-s)+\frac{(e_c-e_{x1})\epsilon^{-ph}}{T_e\left(p+\frac{1}{T_e}\right)}\right]+p\,e_d'{}_1 \qquad (17)$$

or

$$e_d'=\frac{(e_{x1}-s)}{T_{do}'\left(p+\frac{1}{T_d'}\right)}+\frac{(e_c-e_{x1})\epsilon^{-ph}}{T_eT_{do}'\left(p+\frac{1}{T_e}\right)\left(p+\frac{1}{T_d'}\right)}+\frac{p\,e_d'{}_1}{p+\frac{1}{T_d'}} \qquad (18)$$

Substituting equation 18 into the Bromwich-Wagner complex integral, we get

$$e_d'=\frac{1}{2\pi i}\int_{Br_1}\frac{(e_{x1}-s)\epsilon^{tz}dz}{T_{do}'\left(z+\frac{1}{T_d'}\right)z}+\frac{1}{2\pi i}\times\int_{Br_1}\frac{(e_c-e_{x1})\epsilon^{-zh}\epsilon^{tz}dz}{T_eT_{do}'\left(z+\frac{1}{T_e}\right)\left(z+\frac{1}{T_d'}\right)z}+\frac{1}{2\pi i}\int_{Br_1}\frac{e_d'{}_1\epsilon^{tz}dz}{\left(z+\frac{1}{T_d'}\right)z} \qquad (19)$$

Evaluating the integrals and simplifying, we get

$$e_d' = \frac{T_d'}{T_{do}'}(e_c - s) + \left[\frac{(e_c - e_{s1})T_d'^{2}\epsilon^{\frac{h}{T_d'}} - (e_{s1} - s)}{T_{do}'(T_s - T_d')} \times \frac{(T_s - T_d')T_d' + e_{d1}'T_{do}'(T_s - T_d')}{T_{do}'(T_s - T_d')}\right]\epsilon^{-\frac{t}{T_d'}} - \left[\frac{(e_c - e_{s1})T_d'T_s\epsilon^{\frac{h}{T_s}}}{T_{do}'(T_s - T_d')}\right]\epsilon^{-\frac{t}{T_s}} \quad (20)$$

Differentiating equation 20, setting the result equal to zero, and solving for t, we get the following expression for the time at which e_d' has its minimum value

$$t = \frac{T_d'T_s}{0.434(T_s - T_d')}\log_{10}\left[\frac{e_{d1}'\frac{T_{do}'}{T_d'}(T_s - T_d') + (e_c - e_{s1})T_d'\epsilon^{\frac{h}{T_d'}}}{(e_c - e_{s1})T_d'\epsilon^{\frac{h}{T_s}}} - \frac{(e_{s1} - s)(T_s - T_d')}{(e_c - e_{s1})Td'\epsilon^{\frac{h}{T_s}}}\right] \quad (21)$$

Equation 20 is an expression for e_d' as a function of time after $t = h$. Terminal voltage e_t can be obtained from this expression by use of equation 3.

Appendix IV. Nomenclature

Per-unit values are used for all quantities except where specifically denoted otherwise.

$\epsilon = 2.718$
e_d = direct-axis synchronous internal voltage
e_c = exciter ceiling voltage
e_d' = direct-axis transient internal voltage
e_{d1}' = initial direct-axis transient internal voltage
e_n = nominal exciter voltage
e_t = generator terminal voltage
e_s = exciter terminal voltage
e_{s1} = initial exciter terminal voltage
h = regulator operating time
$H(t)$ = Heaviside unit function
$H(t-h)$ = delayed Heaviside unit function, that is, the function which is zero for t less than h and unity for t greater than h
i = $\sqrt{-1}$ in the Bromwich-Wagner complex integral
p = parameter used in operational form of time-dependent functions
r_a = generator armature resistance
r_{ext} = external resistance, that is, load resistance at generator terminals
$r_t = r_a + r_{ext}$
R = nominal exciter response by American Standards Association definition
s = per unit excitation required to overcome saturation at no load, rated voltage
t = time in seconds
T_d' = short-circuit transient time constant defined by equation 6
T_{do}' = generator open-circuit transient time constant
T_s = time constant of exciter build-up
x_d = unsaturated direct-axis synchronous reactance
$x_{d1} = x_d + x_{ext}$
x_d' = direct-axis transient reactance
$x_{d1}' = x_d' + x_{ext}$
x_{ext} = external reactance, that is, load reactance at generator terminals
x_q = quadrature-axis synchronous reactance
$x_{q1} = x_q + x_{ext}$
z = complex variable parameter used in the Bromwich-Wagner complex integral

Discussion

John G. Noest (Consolidated Edison Company of New York Inc., New York, N. Y.): When it becomes necessary to start a motor load from an a-c generator, where this motor load is a considerable percentage of the generator's capacity, the behavior of the generator voltage is of considerable importance.

This is so, because the starting torque and the pull-out torque of induction motors are proportional to the square of the impressed voltage. Where the starting of motor load from a generator produces a considerable voltage drop, it is important to know whether or not motors, already in operation, will pull out and in doing so further aggravate the condition.

Prior to the publication, in 1944, of part I of the present paper by Messrs. Harder and Cheek,[1] only a cumbersome step-by-step method was available for the solution of this problem.

Part I attacks the problem for the self-excited exciter case analytically and gives sets of curves, which are very helpful, where they apply. The present paper extends the investigation to the separately-excited exciter case.

Part I and II, together, form a complete treatment and the data given therein permits a ready and convenient reference for the solution of such a problem.

Since the calculation work for part I, which apparently was done manually, appears to be about equal to that required for part II, which was done on the analogue computer, I wonder if the authors can give a comparison in terms of time required or cost for the computation jobs.

Reference

1. See reference 1 of the paper.

E. C. Whitney (Westinghouse Electric Corporation, East Pittsburgh, Pa.): This paper is a real contribution to the calculation of voltage dips and points out the improvement in performance by the use of separately-excited exciters with the same nominal speed of response. In the calculations the rated voltage value of transient reactance is used which is a very satisfactory method of calculation but the users of the curves should be cautioned that this value is approximately 88 per cent of the rated current or unsaturated value X_{du}' which is commonly given out when reactance data is requested of the manufacturer. This factor may vary from about 80 to 98 per cent, but is most commonly 88 per cent, which is the value the authors used.

In the determination of e_c/e_n, the value of nominal exciter voltage of 2.4 is very satisfactory for the average turbine generator and diesel-driven machine with about 0.85 short-circuit ratio and 0.8 power factor. For water wheel generators with 1.0 or higher short-circuit ratio and power factors higher than 0.80, the ratio of 2.4 is reduced considerably and will be approximately 1.4 for a 1.50 short-circuit ratio unity power factor machine. This has the effect of increasing the drop calculated by the curves for a given reactance with the separately-excited exciter. With the self-excited exciter, performance would be improved slightly with small load increments but for large load increments, the voltage drop may be increased or decreased depending on the actual exciter ceiling and load increment. Since water wheel generators are not subject to this type of load increment as often as the other types of machines, the authors' assumption is good for the preparation of general curves.

In the use of Figure 4, the reader should be cautioned that the time constants shown are general tendencies only and a plot of actual machines will show considerable scatter. However, the curves do provide a reasonable basis of assumption for average values and thus are very useful.

G. A. Nagel (Office of the Comptroller, State of Connecticut, Hartford, Conn.): I do not know whether this is a proper question since the discussion seems to be more along the line of design, but I would like to ask the authors what their experience has been in connection with voltage control for X-ray equipment. We are having trouble due to voltage drop when using a Skinner steam engine and turbine supplying a common bus. With diagnostic equipment we

frequently lose pictures and in connection with deep therapy the condition is especially serious, as we are limited to a variation in radiation output of not over 15 per cent.

E. L. Harder, R. C. Cheek, and J. M. Clayton: The authors appreciate the additional contributions to this subject offered by Mr. Whitney. He brings up the point that the unsaturated value of transient reactance, x_{du}', is the value commonly given out as the transient reactance of water-wheel generators and salient-pole engine-driven generators when reactance data is requested of the manufacturer. For the calculation of critical cases, the user should request the manufacturer to supply the saturated or rated voltage value of transient reactance, since the curves are plotted on this basis. In all cases, however, results obtained by entering the curves with the unsaturated value will be pessimistic and hence the error will be on the safe side.

Differences in the ratio e_c/e_n may affect slightly the results obtained with a given response ratio, but the response ratio itself takes this factor into account by definition, and variations resulting from different ratios of e_c/e_n should have only a secondary effect upon the results.

With regard to Mr. Nagel's question, the curves do not take into account the effect of speed change of the prime mover, and a correction for this factor would have to be made separately in using the curves.

Mr. Noest asked for a comparison of the time required for the computation of the curves presented in this paper, as compared with the time required for the computation of the similar set of curves in the previous paper. The use of the analog computer made it possible to reduce the computation time to about one-fourth that required in the previous case, although the time required for manual calculation in this latter case would have been about equal if the Anacom had not been available.

A New Grounding and Testing Device for Metal-Clad Switchgear

H. KRIDA
ASSOCIATE AIEE

E. T. McCURRY
ASSOCIATE AIEE

THIS paper describes a new improved type of grounding and testing device for use in metal-clad switchgear of the type shown in Figure 1 in voltage ratings of 4,160 and 13,800 volts. With this device, checking and grounding functions incidental to the installation of the switchgear and operational maintenance of connected cables and other electric apparatus can be performed easily and safely.

It consists of a unit which is mechanically interchangeable with, and which uses the same vertical lift elevating mechanism as a corresponding type of power circuit breaker. The primary disconnecting contacts also are similar to those provided with the power circuit breaker, except that removable ball-type contacts are provided on the bushing studs to permit using the device in circuit breaker metal-clad compartments designed for 600-, 1,200-, or 2,000-ampere power circuit breakers.

Functional Requirements

In the course of placing into service or subsequently testing the power circuits and electric apparatus (busses, feeders, incoming and tie lines, power transformers, generators, and the like) connected to the two sides of the power circuit breaker, it is often desirable or necessary to perform functions of the following nature:

1. Check the presence or absence of voltage on either the bus or the line, preliminary to grounding or other testing operations.

2. Check either the relative phase sequence between both sides of the circuit or the actual phase sequence on each side.

3. Apply a test voltage to either the bus or to the line for the purpose of checking the insulation resistance of the circuits.

4. Connect a resistance measuring device to either the bus or line to measure the resistance of a fault on either circuit in order to determine its proximity to the station.

5. Solidly ground all the conductors on either the bus or the line to insure the safety of operating and maintenance personnel who may work on the grounded conductors.

Analysis of Design Requirements

For open-type switchgear it has generally been the accepted or common practice to make temporary and often hazardous bolted connections from the exposed conductors to the required external apparatus such as potential transformers with necessary instruments, kenetron test set, short circuiting connectors or circuit breakers, and so forth for accomplishing the necessary functions. This practice leaves much to be desired as regards safety to personnel, and ease and time of accomplishment.

Metal-clad switchgear used on voltages from 2,300 to 13,800 volts, due to its design for safety to operating personnel, and in order to confine a failure should this occur, is divided into several isolated compartments in which all of the main connections and busses are completely insulated. There are no exposed conductors accessible for making temporary connections to external apparatus as in open-type switchgear. Consequently, it is impracticable to follow the same procedure as is used with open-type switchgear and it is, therefore, necessary to provide other facilities for performing the necessary grounding and testing functions.

The stationary contacts in the metal-clad housing which are used for plugging in the ball contacts of the circuit breaker element are the points most readily available for making the necessary electrical connections. The logical approach, therefore, is to design a device which will utilize these contacts. Such a device should, in general, fulfill the following requirements:

1. The device should replace its corresponding type of power circuit breaker in the metal-clad compartment, while all of the required testing and grounding functions enumerated previously are being performed.

2. It should be designed so that all of the required functions can be performed with maximum safety to operating personnel. The device should have adequate mechanical and electrical interlocking, dead front features, and provision for remote control.

3. The device, including its external accessories, should be designed for maximum ease in operating and handling, and utilize all of the conveniences provided for handling the circuit breaker including the vertical-lift elevating mechanism in the metal-clad housing.

4. For the testing function, each of the individual bus and line conductors should be provided with a conveniently-accessible point of contact or receptacle for connecting an external source of test voltage to a recognized type of external testing device.

5. For the grounding function it should be possible to short circuit and ground either of the three bus or three line conductors. All parts should be designed to withstand full short-circuit current stresses without damage if the device should accidentally be applied to a live circuit.

6. All of the primary conductors required for the grounding function should be self-contained in the device, so that no external cable connections will be required and so that it will be possible to close and lock the door of the metal-clad compartment with the device in position.

7. The same device should be suitable for use with similar types of 600-, 1,200-, and 2,000-ampere circuit breakers.

8. The device should be capable of performing its grounding function even when control power is not available in the station. For safety reasons, it is desirable that this function be initiated from a remote point.

Paper 50-60, recommended by the AIEE Substations and Switchgear Committees and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted November 2, 1949; made available for printing December 7, 1949.

H. KRIDA and E. T. McCURRY are both with the Switchgear Division of the General Electric Company, Philadelphia, Pa.

Figure 1. Typical installation of metal-clad switchgear equipped with vertical lift removable element magne-blast circuit breakers

Figure 3. Grounding and testing device showing view of selector switch and grounding contact through transparent barrier

Charging handle and selector switch handle in place

Past Practice

There have been previous steps in the development of devices for grounding and testing purposes, but no prior device has incorporated all of the functions in a single unit which would meet the foregoing requirements.

One design consisted of a box with metal-clad power circuit breaker bushings to the lower end of which copper bars were connected. These bars were extended to the front of the box to permit connection of the external testing or grounding apparatus. With this device, the grounding and testing functions were similar to those for open-type switchgear. It fulfilled the testing function requirements better than it did the grounding function requirements, for obviously a separate short-circuiting and grounding device, such as an external circuit breaker should preferably be used to complete the final circuit.

Since the grounding function is in many cases the important one, another design just for that purpose was evolved. It consisted of a power circuit breaker with one set of three specially-designed bushings shortened at the top and provided with a short-circuiting bar connected through a grounding shoe to the ground bus. No testing features were included in this design.

It now has been found possible to combine the functions of both of these devices into one new design, and in addition, incorporate into this new design extra features not heretofore available, making it meet substantially all of the requirements listed previously.

Figure 4. Cross section of grounding and testing device

Figure 5. Power circuit diagram for grounding and testing device

Description

This new device, mounted on four wheels, two of which are swivelled, is shown in Figures 2 and 3. A cross-section is shown in Figure 4, and the primary circuit connection diagram in Figure 5. The ball contacts on top of the bushings are removable and provision is made to use 600-, 1,200-, or 2,000-ampere contacts as required by the metal-clad equipment.

Testing Functions

The testing functions are provided for by means of six receptacles on the front of the device which are connected to the six primary bushings. These receptacles provide a ready means of contacting the bus or line with voltage detectors, leads for insulation testing, or phase checking devices.

Figure 6. Grounding and testing device installed in metal-clad compartment with connections made to test receptacles by means of test plugs

Plugs

Suitably insulated plugs which fit into the receptacles on the front provide a means of connecting test cables to either the bus or line contacts as shown in Figure 6. These may be used in connection with high-voltage a-c or d-c equipment for testing the insulation of the cable or bus. The same plugs also can be used for making connections to resistance-measuring equipment to determine proximity of faults in cables or even to a testing or checking unit containing potential transformers with required secondary devices for checking voltage, phase sequence, and so forth as desired.

The plugs shown in Figure 7 are constructed so that they can be disassembled easily without the use of tools for attaching test cables to the terminals. Unscrewing the ball contact releases the stud to which is attached a bolt-type terminal for connecting the test cable. This terminal is suitable for any size wire up to Number 4 and could, if necessary, be changed readily to a larger-size terminal. The inside diameter of the insulating tube through which the test cable is taken is about two inches, and therefore will accommodate any test cable ordinarily used.

Glow Tube Voltage Detector

An electrostatic-type glow tube mounted in an insulated housing and supported on an insulated handle, commonly designated as a "hot stick" is shown in Figure 7. It has contact plugs suitably spaced to permit simultaneously contacting any two adjacent test receptacles on the grounding and testing device. One of the two contact plugs is threaded to the main support so that it can be turned to a position which will permit contacting a single conductor with one plug.

When both plugs are used, as shown in Figure 8, a means is provided for checking by voltage difference indication across corresponding phase conductors whether the relative phase sequence and the phasing of the two circuits are correct. If they are not correct, there will be a voltage difference across each of the three pairs of conductors and the tube will glow.

The single plug is used to determine the presence or absence of voltage on any conductors preliminary to grounding the circuit.

It will glow if voltage is present.

Figure 7. Test plugs for use in making connections with test receptacles

Double hot stick for use in testing for voltage and phasing on the test receptacles of the device

The usual procedure is to contact a known source of voltage with the plug to determine that the glow tube is operative preliminary to contacting the conductor which it is desired to test. If the tube fails to glow during test, the plug again is contacted with a known source of voltage to insure that the failure to glow during test was not due to tube failure.

Figure 8. Grounding and testing device installed in metal-clad compartment with hot stick in use

Figure 9 (left). Selector switch being manually operated prior to inserting the device into the metal clad compartment

Figure 10 (right). Electrical operation of the grounding and testing device with the control cable

Removable Cover

In order to prevent accidental contact with the testing receptacles at any time when they are not being used, a removable cover hinged from the top is provided, as illustrated in Figure 2. This cover, arranged for locking in position by padlock, blocks access to the receptacles except during the testing period.

Grounding Function

The grounding function is obtained with the following components of the device:

1. Manually-operated and interlocked 3-pole double-throw selector switch, using the lower end of the bushing studs for the stationary contacts.
2. Three-pole grounding contacts operated by a spring charged mechanism, with necessary electrical control and interlocking features.
3. Grounding shoe connection to ground bus inside of the metal-clad switchgear.

Three-Pole Double-Throw Selector Switch

This switch uses the lower ends of the two sets of primary bushing studs as the stationary contacts and transfers these by means of the blades to the stationary ends of the 3-pole grounding contacts.

The selector switch is manually operated by a removable handle, Figure 9, which is inserted at the side of the device. To insure that the switch contacts cannot be used to make or break the ground connection, the switch mechanism is so designed and interlocked that it cannot be operated after the device is inserted into the metal clad compartment.

This is accomplished by providing interference between the handle and stops in the metal-clad compartment so that the handle must be removed before the device can be rolled into position.

To insure that the switch is completely closed in one of the two operating positions before insertion into the metal clad compartment, the design is such that the handle cannot be removed with the switch in an intermediate position.

The position of the selector switch is indicated on the front of the device by means of a mechanically connected target reading either "bus" or "line." Transparent covers on the sides and barriers of the same material between poles (as shown in Figure 3) provide for visually checking the position of the selector switch prior to rolling the device into the metal-clad compartment.

Three-Pole Grounding Contacts and Operating Mechanism

Main and Arcing Contacts. The hinged side of these contacts connects to the grounding shoe on the device and the stationary contacts connect to the hinged contacts of the selector switch as shown in Figures 4 and 5. In closing, these contacts perform simultaneously both the grounding and short-circuiting functions.

Both main and arcing contacts are incorporated, the latter for decreasing the burning on the main contacts should they accidentally be closed on a line which has not been de-energized. The main contacts are surfaced with silver and the arcing contacts are surfaced with arc resistant material. Both sets of contacts and all other parts are designed to withstand the mechanical forces and to close and latch on the maximum available short-circuit currents associated with the rating of the equipment.

The contacts have not been designed for any interrupting duty and therefore no arc chutes are provided. In case the grounding contacts should be accidentally closed on a live line, other circuit breakers on the system must remove the fault.

The position of these contacts also is indicated on the front of the device by a mechanically-connected target reading either "open" or "closed." The transparent covers and barriers mentioned previously in connection with the selector switch also permit checking the condition and position of the grounding contacts prior to rolling the device into the metal-clad compartment.

Manually-Charged Spring-Operated Mechanism. The grounding contacts are operated by a manually-charged spring-operated mechanism. This mechanism has already been described, in a previous AIEE paper.[1] It is inherently well adapted for this application because it can be used independently of a control power source. It can be operated at any time, even when control power may not be present in the station.

The mechanism provides adequate power for closing the contacts and latching them closed against full rated momentary current corresponding to the circuit breaker rating which it replaces. An inherent feature in the mechanism is that the closing operation cannot be initiated until it has reached the fully-charged position preliminary to closing. This feature insures full power for all closing operations.

The mechanism is located at the rear of the device and must be charged before the device is inserted into the metal-clad compartment. Hence, it will supply only one closing operation after it has been inserted into position in the compartment. This arrangement is, of course, a result of available space limitation but it is not believed that from a practical stand-

point that this single-operation feature is objectionable. Grounding of a circuit is an infrequent and deliberate act, and this single-operation feature actually provides effective interlocking against accidental reclosure of the grounding contacts once they have been opened.

The mechanism can be operated to close the grounding contacts by pulling a release lever located on the front of the unit. This lever is in the shape of a ring, to which a cable or lanyard may be attached, thereby permitting its operation from some distance away from the switchgear. By this means, the same degree of safety is obtained as would be the case when operation is initiated electrically by the control push button connected to the control cable.

Electrical Control and Interlocking Features. The mechanism is provided with separate electrical release features and coils for the closing and opening operations, respectively. These coils can be wound for either a-c or d-c control power as required.

For remote electrical operation there is provided a control cable, Figure 10, with a push-button station, a plug for connecting to an electric outlet to supply the control power, and another plug for use on a receptacle in the front of the grounding and testing device for connecting to the release coils. The control connections are shown diagrammatically in Figure 11. A removable handle control transfer switch with three positions, namely, "close," "off," and "trip," and with mechanical interlocking features, determines by means of its contacts whether the remote push-button station is to perform the closing or opening operation. This feature insures that the remote operator can perform only the one operation

that was intended, and cannot accidentally also perform the other. When this transfer switch is placed in the "close" or "off" positions, the mechanical interlocking through bevel gears and a stop, Figure 12, physically blocks the mechanism trip latch, so that the main contacts cannot trip free during the closing operation, and so that the mechanism will be blocked closed except when tripping is actually desired. When this transfer switch is placed in the "trip" or "off" position, mechanical interlocking is provided through the bevel gears and notched segment to prevent manual release of the mechanism to close the grounding contacts.

The handle of the transfer switch is removable only in the "off" position, and by this means any unauthorized electrical or manual closing or electrical opening of the grounding contacts can be prevented. As an added safeguard, padlock hasps are provided for the purpose of preventing unauthorized manual closing or opening operations regardless of the position of the transfer switch. When the device is padlocked to prevent manual opening of the grounding contacts, it also is locked so that the device cannot be lowered in the metal-clad compartment. Unauthorized operation also can be prevented by providing a key lock on the door of the metal-clad unit and locking the door.

Through the interlock trip lever, Figure 12, provision is made for automatically opening the grounding contacts should the device be raised into position in the metal-clad compartment with these contacts in the closed position. This same trip lever interlocks the device with the metal clad to prevent closing of the grounding contacts while the device is in an intermediate position in the metal-clad compartment.

Grounding Shoe Connection to Ground Bus

When the grounding and testing device is raised to the operating position in a unit of metal-clad switchgear, the grounding shoe which consists of a sliding contact on the device, engages a contact on the stationary structure which connects the hinged side of main grounding contacts to the ground bus in the switchgear. This eliminates the necessity for any external cable connections during the period that a circuit is grounded and permits closing the door to the compartment. Thus, there is no interference or hazard to attendants in operating the rest of the apparatus in the switchgear and station, and unauthorized or accidental removal of the grounding connection is prevented.

Tests

Tests have been made to assure that both the 4.16 kv and 13.8 kv forms of the device, as shown in Figure 13, will meet the maximum momentary current requirements and the close and latch requirements against momentary current. The required current values for the ground and test device is considered to be equal to the rating of the circuit breaker with which it is used. The momentary current values which have been exceeded by tests are shown in Table I.

Table I

Rated Voltage	Rated Mva	Momentary Current-Amperes
4.16	150	40,000
4.16	250	80,000
13.8	250	35,000
13.8	500	40,000

Conclusion

The high degree of operational safety and reliability which characterizes metal-clad switchgear has been extended to the recognized functions of circuit testing and maintenance by means of this improved grounding and testing device. Inconvenient and cumbersome makeshift methods of dubious safety need no longer be resorted to and grounding testing of circuits now can be quickly and safely affected.

Discussion

O. B. Vikoren (Philadelphia Electric Company, Philadelphia, Pa.): The authors and the General Electric Company are to be congratulated on having developed a combination grounding and testing device which holds forth promise of being acceptable to the majority of users of metal-clad switchgear, either in the form described in the paper or with relatively minor modifications. The device is very interesting because it embraces important safety features which have been lacking in some of the devices which formerly have been developed for grounding and testing purposes.

The question may be raised, however, whether the designers of the new grounding and test device have taken full advantage of the opportunity to incorporate all the safety features which can be built into the device without adding extra parts. Since the human element cannot be eliminated, have they considered fully the consequences if an error is introduced in connection with the use of the device?

For example, if in the process of grounding a line, an operator should overlook the correct position of the selector switch and leave it in the bus position as shown in Figure 4, he may, by detecting no potential on the line test terminals with a glow detector, be convinced that the line is de-energized and close the grounding switch. The result will be a 3-phase short circuit on the bus. Since the closing of the grounding switch is intended to be done only from a remote location and the device is designed to close against short-circuit currents corresponding to the maximum current rating of the associated switchgear, the operator can do no harm to himself. This is, of course, of primary importance; but nevertheless he has created a disturbance to the system which could have been prevented.

In keeping with the operating practice of many utilities would it not be better to have provision to always make the test for voltage at the same set of terminals and at the place electrically where the ground is applied? Can the flexible leads to the test terminals be rearranged to connect the upper test terminals to the front bushings which in turn engage with the bus, and the lower test terminals to the hinge of the selector switch? If, with this arrangement, the same mistake should be made in regard to the selector switch position as was indicated above in connection with grounding of a line, it is unlikely that the operator would close the grounding switch because the assumed test with the glow detector would indicate potential at the stationary contact fingers with which the grounding switch would engage on closing. The confusion during testing is greatly reduced since only the lower test terminals will be used for the detector test prior to applying the ground. Furthermore, the upper test terminals can be blocked except during phase checking tests, by arranging the protective cover for the test terminals in two parts with a key interlock between the upper part of the cover and the line position of the selector switch.

It is not clear from the description of the phasing out facilities in the text and Figures 7 and 8 whether a complete phaseout test can be made, keeping in mind that in phasing out two circuits a reference point common to both circuits is necessary. For example, when phasing between two permanently grounded systems, the reference is provided by the ground connections, but if one or both systems are ungrounded, it is necessary to provide a common reference connection during the test. Even when testing between two normally grounded systems, it is essential that the test indicates whether the ground connections are intact.

Since this device contains many parts which appear to have been adopted from other components of metal-clad switching equipment, it is likely that the device could

be manufactured on a production basis, which in turn would mean that the user eventually should receive considerable benefit. This will be favorably received because the grounding and testing devices developed previously are expensive.

J. M. Graff (Consolidated Gas, Electric Light and Power Company of Baltimore, Baltimore, Md.): This new grounding and testing device for metal-clad switchgear contains many valuable features, such as means of phasing and positive grounding in case of grounding a live circuit through error, that were not available on previous devices.

The first device used on our system consists of a circuit breaker frame with six bushings. Copper straps are brought out from the lower end of these bushings to a point near the front of the device. Access to these straps is by means of separate doors to the bus and line sections. Our practice is to install this device in the compartment, make a test for potential and if no potential is shown, to fasten portable ground leads to the circuit to be grounded. For phasing, both doors are left open and our phasing device used.

The next device consists of a circuit breaker frame with only three bushings. These bushings can be moved as a unit to connect the device to either the bus or the line with an indicator in the front of the device to show the position of the bushings. A manually-operated disconnecting switch provides the grounding facilities. With this device, phasing out facilities are not available, but tests can be made for potential.

A third device in use on our system also has three bushings and a motor-operated disconnecting switch. It is equipped with three potential transformers and relays so that the motor can not close the disconnecting switch if potential is on the circuit to be grounded. In addition, three neon lamps connected across the secondary of the potential transformers provide visual means for indicating potential. A test switch is wired in the lamp circuit so that the lamps can be tested from the 125-volt d-c supply to the motor. This device also does not provide means for phasing out but tests can be made for potential. It is remotely operated by push-buttons on an extension cord.

We have purchased but have not as yet obtained one of the devices outlined in the author's paper but on future orders, we will probably request that two additional features be incorporated.

First, that an additional set of three test sockets connected to the centerpoint of the selector switch be provided so that a final check for potential can be made on the circuit to be grounded.

Second, that means be provided to charge the spring mechanism from the front of the device. On some jobs, it is necessary to remove the ground for low-voltage testing and then to restore it. With the device as described, it is necessary to remove it from the compartment, charge the closing mechanism and reinstall it in the switchgear. The two modifications just suggested should improve the safety and versatility of the grounding and testing device.

B. M. Carothers (Union Electric Company of Missouri, St. Louis, Mo.): That there is need for a grounding and testing device is well recognized by anyone who has had occasion to perform any of the various test operations or provide a substantial power circuit ground in metalclad switchgear. The various functional requirements are well set out. The design of a single unit to satisfy all these needs is an ambitious undertaking. The paper and illustrations are quite clear on all the various features.

One rather common operation will be somewhat inconvenienced due to the storage of energy for only one close-open operation of the grounding contacts. When a cable is to be swung to another circuit, or crotched, safety requires a ground at the terminus during cutting. Then, when the conductors are bared, it is necessary to apply low voltage from the station for phase identification by the splicer at the cut. When phases have been tagged, it is then necessary to re-establish a protective ground during completion of the splice. This will require that the station operator remove the device from the cell for recharging the closing mechanism after phase identification has been obtained.

As indicated in Figure 4, it is necessary that line side conductors be brought forward between bus side bushings to the front test couplers. This would appear to reduce the dielectric margin of the device as compared to the simpler box-type unit where these conductors were completely isolated. This was possible by dropping line leads down then across under those of the bus and reversed configuration of test couplers. Data is presented to indicate that momentary current capabilities are adequate. Does the same reserve in dielectric strength exist?

It is the writer's opinion that need for grounding of busses is so rare that inclusion of the double-throw selector switch is questionable. Considerable simplification could be achieved if bus grounding were not required. It may be that this feature is desirable in operating arrangements with which we are not acquainted.

Recognition of need for safety is evident in the various protective arrangements. Even so the operator must be cautious at all times due to the great number of possibilities of hazard. There is some likelihood that complexity of the device offsets a part of the safety designed into the unit.

B. I. Hayford (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The authors describe a novel metal-clad accessory device which combines the functions of grounding through a power operated closing switch with phase out and testing features in the one device which is physically interchangeable with the metal-clad circuit breaker unit. Combining the functions of grounding either the bus or line with the testing functions seems to make the device unnecessarily complicated, particularly since it is not used in every day operation once the initial installation has been completed. During the installation period, while the device is in frequent use the operators will become familiar with it and proceed in a routine manner without loss of time, but when it is used infrequently, as will be the case when the station is in normal service the operator will need to take time to freshen up on the instructions to make the necessary setup.

Such operations are apt to be under emergency conditions when the system is in trouble and any lost time may be serious.

The use of the manually-charged spring mechanism is discussed in the paper. Because of its location in the rear, it must be charged before the device is placed in the housing and is then good for only one grounding operation. This feature is cited as an advantage as it automatically guards against accidental reclosure of the grounding device. However, it is not clear why accidental reclosure of the grounding device is any more of a hazard than the possibility of an accidental initial closure.

Consider the case of a cable circuit grounded for work. It may be desired to release the ground for preliminary testing and then reapply the ground to complete the job. With the method of operation described in the paper it would be necessary to remove the device from the housing to recharge the spring mechanism before the circuit could be regrounded. The 1-shot grounding feature of the manually-charged spring mechanism appears to defeat the original purpose of combining the test and grounding functions in the one device to eliminate the necessity of handling different devices in and out of the housing during the progress of checking, repairing, and testing the cable circuit. Electrical operation from the station battery would permit opening and restoring the ground as often as necessary during the progress of repairs and testing without removing the device from the housing.

The use of a double-throw selector switch to make the setup for grounding either the bus or line necessitates bringing both sides of the circuit into the same compartment at the switch contacts. Fundamental barriers in the metal-clad structure separate the bus and line compartments. In this respect the combination grounding and testing device described sacrifices the safety barriers possible in the simple device used in the past which permits complete isolation of the bus and line portions of the circuit. This isolation is particularly desirable when using the testing functions of the device for applying kenetron or similar over-potential tests to the cable circuit. This overvoltage test potential will appear in the same compartment as the exposed live bus contacts and only a few inches away at the selector switch contacts. This is an undesirable condition if not an actual hazard when it is considered that workmen will be in close proximity to the equipment during the testing procedure.

The problem of grounding and testing circuits is receiving more and more attention among both the purchasers and manufacturers of metal-clad switchgear. Devices have been built to meet various users requirements ranging from a simple 3- or 6-bushing device to some very elaborate power operated devices with complicated interlocking. The simplest is of course the 3-bushing device which merely brings the circuit live parts out into barriered compartments where they are accessible for checking and attaching ground connections in the same manner as used with previous open structures. At the other extreme, one very elaborate device consists of a motor-operated grounding switch with potential transformers, signal lights and interlocking relays which prevent closing the switch on a live

circuit. Another arrangement consists of an interposing device which placed in the housing ahead of the circuit breaker unit permits grounding through a standard circuit breaker. There is less uniformity in practice and opinion on circuit grounding than on almost any other operating requirements. Replies to committee questionnaires on switchgear practice show this. It is hoped that as this subject receives more study through Institute papers and those of operating engineer associations, that some standardization will develop to guide the users and manufacturers toward a solution of this problem which will be generally acceptable to the industry whether it may be along the lines discussed in this paper or by some other approach.

J. F. Chipman (Allis-Chalmers Manufacturing Company, Boston, Mass.): The authors should be complimented on a comprehensive description of this new grounding and testing device for metal-clad switchgear. The device appears to offer to the users of this class of equipment a much improved, safer, and more economical means of performing the various test functions necessary to efficiently install and maintain their switchgear.

While the paper leaves little to the imagination, I would like to offer the following comments.

First, would it not be desirable to have this device capable of more than a single grounding operation without racking it down and completely removing it from the cell, since in cases involving repairs, the work pattern frequently follows a sequence such as test, then ground for safety while making adjustments or repairs, then unground and test, and more often than not, reground while either taking further corrective measures or while equipment is made ready for re-energization. In case of an outage where two or more grounding operations are required, the single shot device may entail loss of valuable time for recharging. Possibly arrangement for power closure would offer a solution to this operating limitation. This would, of course, require that control power be available to operate the grounding device, but this latter could prove to be a form of insurance since it would prevent inadvertent short circuiting of a bus at a time when no control power is available to trip the bus-feeding circuit breaker or circuit breakers in the switchgear. Otherwise, to clear such a short circuit would require de-energizing external feeders which might involve an outage not restricted to the switchgear alone but including everything served by the back-up circuit breakers. Inadvertent tripping of such a grounding device as described by the authors under these circumstances could be very dangerous if the back-up protection included automatic reclosing.

It is recognized that for safety purposes the device must be provided with adequate interlocking to eliminate insofar as possible the element of human error. The paper states that with the transfer switch in the "off" position and the handle removed, unauthorized electrical opening or closing, and manual closing of the grounding device is prevented. It further indicates how the trip mechanism is blocked to prevent trip-free operation on closing and to prevent tripping unless actually desired, but it does not specify whether or not the grounding contacts can be manually tripped when the transfer switch handle is removed. If the removal of this handle is to serve every purpose, it should thereby prevent all operation with the possible exception of tripping by the vertical lift interlock. To be fully effective the trip interlock lever, which is actuated upon raising the grounding device in the gear, must be able to open the grounding contacts regardless of the position of the transfer switch, but when the grounding device is fully elevated into operating position, the trip lever of Figure 12 should be fully shielded to prevent tripping by manual actuation, deliberate or otherwise. Such provisions may exist although they are not specifically mentioned in the paper.

E. A. Bishop (Commonwealth Edison Company, Chicago, Ill.): The utility companies have accepted metal-clad switchgear for many of their switching substations. As the first units were designed for industrial use the procedures required for checking, testing, and grounding were not present in the metal-clad gear. Much thought has been given to protect the operators from gaining entrance to live parts and promoting safety by interlocks.

The utilities requirements are special because of the widespread distribution system which connects to the switching center and because of the several working divisions which are involved in the installation, operation, and repair of the switchgear or the distribution cables connected thereto. There are several procedures and requirements for safety and checking of the switchgear and cables, which most utilities require before any cables or feeders are made alive for service. Likewise, when any feeder is taken out of service for inspection, repairs, or other work there are definite safety provisions which must be followed. This also is true of the switchgear.

Some of the requirements which are necessary are set forth below:

1. Grounding of any feeder cable leaving the metal-clad switchgear.

2. Grounding of the busses for work on the switchgear.

3. Provision for applying voltage to either bus or feeder cable for phase checking, high potential testing, or cable fault location.

4. Means of checking safely either bus or feeder cable potential.

The new grounding and testing device for metal-clad switchgear fills a need which has existed since the first use of utilities of metal-clad switchgear in that it combines in one unit the facilities which formerly required the use of two separate devices. The result is one less piece of equipment to occupy valuable floor space.

The fact that the spring-operated mechanism is in the rear of the device makes it necessary to remove the device from a compartment each time it is required to close it to ground. This is particularly tedious in locations where the device must be cranked by hand to or from the operating position.

H. Krida and E. T. McCurry: The authors are very gratified with the widespread interest manifested in the new grounding and testing device. The discussions do not indicate a unanimity of opinion on some of the features of this device but are generally in agreement regarding the need for a device incorporating the functions for which it is designed.

Mr. Vikoren suggests that the upper test receptacles be connected to the bus, and the lower set to the hinge contact of the main selector switch. This change in connections could readily be made, but it is doubtful whether this slight advantage would offset some other disadvantage. If the main transfer switch were closed to the bus contacts at a time when it is desired to perform relative phase sequence checking operations, or similar test functions, the resulting indications would be misleading because both sets of test receptacles would be connected to the same electrical points. It would seem that there is less chance of confusion if all receptacles are permanently connected to known sources.

Mr. Graff suggests the addition of three separate test receptacles connected as suggested by Mr. Vikoren. This would add to the complexity of the device out of proportion to the advantage gained. Too many receptacles could become confusing to an operator and would increase rather than minimize the chances of checking the wrong conductors preliminary to closing the grounding contacts. Mr. Carothers suggests that the device is already too complicated.

Mr. Carothers and Mr. Hayford both question the omission of fundamental barriers between components of this device. The insulation between the line and bus conductors is consistent with the insulation level of the corresponding type of power circuit breaker and class of metal-clad switchgear. It is expected that any overvoltage tests applied to the cable or bus will be within these limits. In order to provide complete facilities for testing and checking phase relationship, both the bus and line must be made accessible.

Mr. Carothers states that need for grounding the bus is so rare that the main selector switch could be eliminated in the interest of simplicity. This view is evidently not shared by all users of this type of device, because the majority indicate that facilities for bus grounding are necessary.

Mr. Chipman suggests the addition of a shield over the trip interlock in order to prevent manual tripping when the device is in the raised or operating position. Provision has been made to padlock the mechanical trip to prevent accidental or unauthorized tripping of the ground contacts. If the trip mechanism were shielded in the operating position, it would be impossible to trip the ground contacts manually. Conceivably, it may be necessary to open these contacts even if no control power source was available for tripping electrically.

Mr. Bishop and several other discussion papers described the desirability of providing for more than one closing operation of the grounding contacts without the necessity of removing the device from its housing for recharging the mechanism. Charging the mechanism from the rear was considered desirable as an interlock, or added safety

feature, which would more than offset the inconvenience of removing the device from its housing for recharging in those cases where more than one grounding operation was required. An investigation will be made, however, to determine whether provision for more than one operation could be incorporated without sacrificing some safety features for this added convenience.

Mr. Vikoren brought out the fact that this device was largely made up of parts common to other equipment currently being manufactured, and therefore, it should be possible to produce it at a reasonable cost. From the start, this has been one of our objectives. This advantage, however, can be largely defeated if it becomes necessary to incorporate special features for individual users.

Cost, in a large measure, is determined by the possibility of repetitive manufacture of a single design. Conceivably, it would be possible to produce a single device incorporating all functions prescribed by several users at less cost than would be possible if some of these features were omitted when they are not required.

In designing this device, an attempt was made to incorporate the major requirements of a great many users, with their varying operating procedures. This necessarily resulted in some compromises. To us it seems that the same problems of grounding and testing would apply to all operating companies, and therefore, a single device should be capable of providing all the facilities necessary to perform the functions associated with testing, grounding, and so forth.

In those cases where a user's operating practice differs substantially from the majority, thereby requiring facilities not provided in the standard design, it will be necessary to consider a special design for that user, rather than to incorporate these features in all cases. It is hoped, however, that a single device will meet all essential requirements.

A New 69-Kv Oil-Blast Circuit Breaker

E. B. RIETZ
ASSOCIATE AIEE

C. J. BALENTINE
NONMEMBER AIEE

Synopsis: All recent circuit breaker developments in the higher voltage transmission field have included such features as faster fault clearing, faster reclosing after faults, reduced oil requirements, and reduced maintenance. This paper describes the development of an improved line of oil-blast circuit breakers incorporating these features at 69 kv. The new circuit breakers as compared with superseded designs are smaller, require less oil, have improved oil-blast interrupters, use sealed bushings without gaskets, have a simplified top frame and linkage design, and use air operators. Complete laboratory tests have been made to check the electrical and mechanical characteristics of these new circuit breakers. These tests then were supplemented by actual field tests at 66-kv interrupting staged short circuits over a wide range of currents as well as switching the capacitance current of long unloaded 66-kv lines.

TEN YEARS ago 8-cycle operating times were considered adequate for most oil circuit breakers at all voltages. Since that time, however, the advantages to be obtained from higher speed operation in the higher voltage transmission field (115 kv and above) have become widely recognized. Among these advantages are:

1. Improved system stability by faster fault clearing.

2. Reduction in damage to equipment at the point of fault.

3. Reduction in reclosing times to 20 cycles or less, thereby improving service continuity and further increasing system stability.

4. Reduction in oil requirements and tank sizes made possible by the shorter arcing times and more efficient interrupters which reduce oil carbonization.

5. Reduced contact deterioration.

To secure these advantages of higher speed operation, considerable development has taken place in the past ten years in higher voltage transmission circuit breakers (115 kv and above). In addition, the circuit breakers developed to obtain these faster operating times have included many mechanical and electrical improvements, such as completely sealed bushings, simplified operating mechanisms, greater interchangeability of parts between ratings, simplified assembly and alignment, and increased mechanical life.

A review of the advantages to be obtained from higher speed operation and the improved operating characteristics which have resulted indicate that most of these advantages are just as desirable at 66 kv and below as they are in the higher voltage field of 115 kv and above. A new 69-kv oil circuit breaker has been developed and is shown in Figure 1. The specifications set up for this new circuit breaker were:

1. General—Applicable American Standards Association, Association of Edison Illuminating Companies, and National Electrical Manufacturers Association specifications to be followed in order to meet the requirements of good practice and accepted standards.

2. Voltage—A basic insulation level of 160-kv 60-cycle withstand and 350-kv impulse-voltage withstand.

3. Interrupting Ratings—1,000-, 1,500-, 2,500-, and 3,500-megavolt-ampere interrupting ratings in accordance with new American Standards Association standards with the maximum number of interchangeable parts between ratings.

4. Continuous Current Rating—600 and 1,200 amperes with the circuit breaker to be designed for the maximum rating of 1,200 amperes.

5. Interrupting Time—Nominal 8-cycle rating, with the circuit breaker and interrupters to be designed for not more than five cycles, with appreciation of the fact that three cycles would be desirable.

6. Reclosing Time—Nominal 20-cycle rating, but as short a time as possible should be obtained.

7. Size—Minimum diameter tank consistent with required electrical performance in order to reduce volume of oil to be filtered to a minimum.

8. Maintenance Requirements—Minimum carbon generation to reduce oil maintenance. Insulation members to be designed so that they are not affected by operating conditions, that is, bushings to be sealed and other insulation material to be designed for minimum atmospheric deterioration. Internal insulation surfaces to be designed to retard carbon deposition. All parts to be designed for long mechanical life with constancy of adjustments. Parts requiring regular inspection to be designed for easy checking.

Features of the New Breaker

Development of New Dual-Flow Cross-Blast Interrupter

The interrupting ability of the original radial oil-blast contacts had been well demonstrated by laboratory tests and field operations through the years, but shorter interrupting times and improved interrupting performance required a substantial reduction in arc duration and energy. The inherent simplicity of the contact arrangement using two sequential arcs to secure the necessary oil-blast action was obvious, so the problem reduced itself to designing an interrupting structure which would give substantial reductions in the lengths of the two arcs.

Since the duration of the interrupting arc is dependent on the oil-blast action, it became necessary to provide for a more efficient utilization of the oil flow caused by the pressure generating arc. Recent developments had shown that cross-blast oil flow was more efficient than radial-blast in this respect. Therefore, an arrangement of baffles was added in the region of the interrupting arc to provide for

Paper 50-61, recommended by the AIEE Switchgear Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted August 13, 1948; made available for printing December 7, 1949.

E. B. Rietz and C. J. Balentine are both with the General Electric Company, Philadelphia, Pa.

We wish to express our appreciation to the Pennsylvania Power and Light Company for their cooperation in making available their system and facilities for this contribution to the industry, and to their engineers and operating personnel who materially assisted in the successful culmination of the field tests.

Figure 1. New 69-kv oil-blast circuit breaker, showing simplified design of top frame, solder-seal bushings, and portable tank lowering device

a movement of oil into the arc at right angles to it. Of the baffle arrangements that were tried, the most effective proved to be the dual-flow cross-blast arrangement shown schematically in Figure 2. The dual-flow converges simultaneously from both sides on the arc and sweeps the arc products out at right angles in both directions.

The pressure generated by the upper arc is a function of the current to be interrupted. This resulted in the problem of controlling the pressure generated at the higher currents. Therefore, a baffle structure was added which surrounds the pressure-generating arc and stabilizes it in a straight line between the two contacts. This limits the arc energy liberated for a given contact spacing to a minimum. It also eliminates magnetic looping of the arc which insures close duplication of pressure on each operation when interrupting the same current.

Figure 3 shows a cutaway view of the new interrupter. The upper and intermediate contacts are enclosed in a heavily walled insulation tube which is fastened readily to the metallic adapter mounted on the lower end of the bushing. This insulation-tube enclosure replaces a metallic chamber which had to be provided with external and internal insulation linings to prevent the arc striking over to it. All contacts are faced with arc-resisting material to increase their life and reduce maintenance.

The enclosing-tube assembly with the intermediate contact and the two sets of baffles can be removed from the adapter as a unit as shown in Figure 4. Four threaded studs hold it in place. After removal, all interrupter parts are visible for inspection. The contact alignment and compression are not disturbed, so it is not necessary to readjust for these points after reassembly. The moving contact rod is positively aligned by the method used to key its support into the crossbars. It can be adjusted easily to enter the chamber centrally for obtaining contact compression.

Design of Pole-Unit Structure

The best design of pole-unit structure includes a minimum of separate parts and exposed gasket surfaces. Figure 5 is a cross section through the new pole unit showing the top frame supporting the bushings, interrupters, mechanism linkage, and tank.

The improved interrupters permitted a reduction in the tank diameter from 42 inches to 36 inches. This reduced the over-all dimensions and the quantity of oil. As a result foundations can be smaller and there is less oil to handle during maintenance.

The pole-unit top frame consists of a formed-dome welded to a heavy base plate which carries the supports for the mechanism linkage and incorporates the recess for the tank gasket. On the dome are mounted the bushing supports and the standard accessories such as float-type oil gauge, fill valve, oil separator, and emergency vent. The bushing supports have a gasket arrangement which permits tilting the bushings to obtain proper alignment of the interrupters. The top frame provides a support and housing for the bushing-type current transformers. In the new circuit breaker, there are provisions for two transformers for each bushing. This makes possible additional relaying and metering transformers for special purposes. The pole-unit top frames are made up individually and are held in proper relationship to each other by being doweled to the supporting framework. They are so designed for greater ease in handling during fabrication and to

Figure 4 (right). View of interrupter after removal from adapter, showing ease of disassembly and inspection of contacts

Figure 5 (left). Cross section view through a pole unit of the new 69-kv circuit breaker, showing the new solder-seal and easily adjustable bushings base-plated mounted type of linkage, provision for two current transformers per bushing, and the new interrupters in place

Figure 7 (right). Cutaway view of pole-unit mechanism linkage which is permanently fastened to the top frame base plate and which provides straight line contact motion. View also indicates both internal and external stop clearance settings

facilitate arrangements for single-pole reclosing which is sometimes required.

The bushings in Figure 6 are of an improved design utilizing the well-known liquid-filled type-*L* construction. The outer weatherproof porcelain shells are soldered to metal fittings at each end, thus eliminating gasketed joints. The terminal connections are silver-surfaced. The exposed insulation at the lower end of the bushing has a special coating to retard carbon deposition which also seals it against moisture absorption.

Each pole unit has its own mechanism linkage, see Figure 7, which provides straight-line contact motion and which is permanently fastened to the top-frame base plate. Reference points for adjustment are available in each pole-unit top frame, but a ready check can be made at the front crank housing without dropping the tanks. Travel recorder connections can be made on each pole unit. Interchange of gas and oil between pole units is prevented by adjustable seals through which interphase connecting rods slide.

Lightweight portable tank lifters which can be readily attached to the framework permit rapid and easy lowering of the tanks for contact inspection without removing the oil. The two tank-lifter units are self-contained, and their cables can be quickly attached to suitable lifting straps on the tank. Two-man operation is required, but this cancels the former laborious task of threading wire cables through pulley blocks and sheaves.

Figure 8. Right-side view of pneumatic trip-free compressed air mechanism, showing the mechanism linkage parts and compressed air-storage tanks

The new smaller circuit breaker permits shipment of a completely assembled breaker except for the lower end sections of the supporting framework which are removed to reduce the height. This makes installation easier because the circuit breaker is received with all factory adjustments and wiring completed. There is little to do in the field except locate the circuit breaker on its foundation and connect to it.

The circuit breaker is operated by a compressed-air mechanism as shown in Figure 8, which is pneumatically trip-free and antipumping when closing on fault conditions. Air operators now have been in service almost ten years and reflect the constant program of improvement during these years. All of the associated air-supply equipment is included within the weatherproof and dust-tight sheet-metal housing. Electrical and air-control units are mounted on a single panel where the front-of-board connections provide ready accessibility for observance and checking. This is illustrated in Figure 9. Heater units, some of which are thermostatically controlled, prevent condensation and give satisfactory cold weather operation down to −40 degrees Fahrenheit. High-speed reclosing of less than 20 cycles is obtained easily on all circuit breakers, and there is sufficient air storage to give at least eight circuit breaker closings without compressor operation.

Proof of Performance

Proof of performance can only be obtained by exhaustive design tests. The following tests demonstrated the adequacy of the design for protection of 69-kv backbone subtransmission systems.

1. Overvoltage tests were made at 60-cycle frequency and impulse voltages. Withstand tests were made at 60 cycles up to 10 per cent above rating or 176 kv to determine the margin of safety with the smaller tank. Impulse voltages up to 529 kv were held. Impulse flashover occurred at 625 kv.

2. Continuous current-carrying heat runs at 1,200 amperes were made indicating a comfortable margin of safety.

3. Operating tests were made to check closing, opening, and reclosing characteristics. Figures 10(A) and 10(B) show travel-time charts of actual no-load circuit breaker operations. Mechanical life tests totalling over 20,000 operations were made on both circuit breaker and mechanism parts without signs of appreciable wear.

4. Extensive laboratory interrupting tests were made on all types of duty previous to the field tests.

Field Tests

After the tests in the factory, arrangements were made to supplement them with field tests on a user's property.

These field tests were of interest because they represented, as far as known, the highest capacity 66-kv field tests ever made. The tests were made at the Siegfried Substation of the Pennsylvania Power and Light Company, which is the center of the 66-kv transmission network of that system. Short-circuit duties up to nearly 1,500 megavolt-amperes could be obtained at that location.

Figure 9. Left-side view of compressed air mechanism, showing electrical and air control units, front connected and mounted on a single panel for easy accessibility

Two series of tests were made, one on a sample circuit breaker of the proposed design for the 1,500 megavolt-ampere rating and the second on new 2,500-megavolt-ampere interrupters installed in a modernized circuit breaker. The new 69-kv circuit breaker was solidly bolted to I-beams which were in turn secured to the transformer track rails in a clear area between the 66-kv and 220-kv yards. All tests were made single-phase line-to-ground. The ground side of the circuit breaker was tied in to the overhead

Figure 10(A). Closing and tripping curves of the new 69-kv circuit breaker, showing the high-speed operation of the air operator

Figure 10(B). Reclosing curve of the new 69-kv circuit breaker, showing a 16-cycle reclosing operation

Figure 12 (right). Station bus setup for 69-kv circuit breaker field tests, showing test circuit breaker connected to Freemansburg Number 2 test line

ground wire on the 220-kv towers except at maximum capacity where the ground lead was connected directly into the station ground mat to the foot of the circuit breaker. Figure 11 shows the circuit breaker set up for test.

The breaker in which the 2,500-megavolt-ampere interrupters were installed was located in the lower 66-kv switchyard.

This circuit breaker had been modernized recently with 8-cycle oil-blast contacts, new pole-unit linkages, and an air operator. The new 2,500-megavolt-ampere interrupters replaced the 8-cycle interrupters, and very little additional work was required to prepare the circuit breaker for test. A similar arrangement of connecting the circuit breaker into the switchyard was used.

Siegfried Substation had been used on previous occasions for short-circuit tests, and the method of applying various fault duties had been worked out to give the least inconvenience and danger to the rest of the system. Faults were applied on the Freemansburg lines at various distances from the substation. From previous calculations, it was known what short-circuit duty would result and, therefore, the required steps of short-circuit current were predetermined. As the tests progressed, from light to heavy currents, the point of fault was gradually moved in from the far end of the line to a final ground at the very base of the circuit breaker. This proved very successful and involved no system or generator switching. Figure 12 shows the station bus setup for the tests.

Magnetic and cathode-ray oscillographs were used to obtain the records during the tests. The magnetic oscillographs measured the three bus voltages, fault current through the circuit breaker, voltage across the circuit breaker, circuit breaker travel, tank pressure, and trip current. A portable cathode-ray oscillograph was set up to measure the line and bus voltages on the line-switching tests and across the circuit breaker on the fault tests. Two capacitance-type 230-kv bushings were located on either side of the circuit breaker and acted as voltage dividers to give voltage indication for the oscillograph. For the tests on the 2,500-megavolt-ampere interrupters, a string of line insulators was used in place of the capacitance-type bushings.

Both the cathode-ray and the magnetic oscillographs were mounted in a truck located approximately 100 feet from the circuit breaker under test. This provided a very satisfactory portable oscillograph house. All leads running from the test location to the truck were properly shielded.

Results of Tests

New 1,500-Megavolt-Ampere Circuit Breaker

In all, 22 fault tests were made in a series, made of Open, Close-Open, Close-Open—15 Seconds—Close-Open, and Open—Instantaneous—Close-Open duty cycles. As part of the 22 interruptions, a special duty-cycle series was made which consisted of an Open—Instantaneous—Close-Open—1 Minute—Close-Open—1 Minute—Close-Open. This latter test was made at the maximum available short-circuit kilovolt-amperes of the station. Figure 13 is an oscillogram of the test.

The currents interrupted ranged from 1,400 amperes on the initial test to a value of 11,900 amperes on the final tests. This corresponds to a range of 160 to 1,400 megavolt-amperes when translated into equivalent three-phase megavolt-ampere. The complete summary of the tests is given in Table I.

The interrupting times were within five cycles on all tests except for the second operation of two instantaneous-reclosing duty cycles.

All types of duty, including the special one, were handled with ease. There was no external sign of disturbance, the only indication of circuit breaker operation being the movement of the circuit breaker position indicator.

Otherwise there was no means of telling that an operation actually had taken place.

Oil samples were taken throughout the tests, and although the oil became slightly discolored as the program progressed, the oil tests did not disclose any appreciable amount of carbon present even at the completion of the series.

Examination of the contacts, which are illustrated in Figure 14, showed some burning of the arcing surfaces. Their general condition, however, was good, and they undoubtedly could have withstood a similar additional series of tests.

A series of line-dropping tests was conducted on 24, 50, and 70 miles of line. Interruptions were prompt on all tests, the maximum time being 3.4 cycles to final clearing of the circuit. Although some restriking occurred on these tests, the maximum overvoltages in all cases were limited to less than twice the peak value of the test voltage.

New 2,500-Megavolt-Ampere Interrupters

The schedule of tests was essentially the same as that followed on the initial series. A total of 21 fault tests were made. The special Open—Instantaneous—Close-Open—1 Minute—Close-Open—1 Minute—Close-Open duty cycle was repeated. Figure 15 is an oscillogram of this operation. The currents interrupted ranged from 1,340 to 12,500 amperes corresponding to an equivalent 3-phase megavolt-amperage of 150 to 1,400 megavolt-amperes. The complete summary of results is given in Table II. This represents a coverage of from 6 to 56 per cent of rating. Together with the data from laboratory interrupting tests up to 28,000 amperes in the arc, this indicates the ability of the interrupter to handle its interrupting rating.

All interrupting times were within five cycles except for the second operation of instantaneous-reclosing tests. The interrupters cleared all faults with ease, showing no visible signs of disturbance. The oil was in excellent condition at the completion of the tests, and the arcing surfaces on the contacts pictured in Figure 16 showed only very moderate burning.

A series of line-dropping tests was also made on this interrupter. A maximum interrupting time of 2.6 cycles was needed to clear 24, 50, and 70 miles.

Final Laboratory Interrupting Tests

The field tests on both the new circuit breaker and new interrupters confirmed the initial factory tests in showing that the second operation of an instantaneous-reclosing duty cycle had slightly longer interrupting times. Further development in the laboratory after the field tests

Figure 16. Condition of the contacts on the 69-kv 2,500-megavolt-ampere interrupters after interrupting 21 fault currents. The slight burning indicates they would have been capable of many more operations without maintenance

Figure 17 (right). Plot of representative laboratory tests on final 1,500- and 2,500-megavolt-ampere interrupters with voltages of 66, 44, 22 and 14.5 kv across a single pole unit. 20-cycle reclosing tests are included. 5-cycle circuit breaker performance is shown for all duty cycles

showed that the performance on the second operation of an instantaneous-reclosing duty cycle could be shortened by a simple rearrangement of the baffles in the vicinity of the interrupting arc. Tables III and IV are summaries of the interrupting test data on the final designs of the 1,500- and 2,500-megavolt-ampere circuit breakers. These data, plotted in Figure 17 for all types of duty cycles, show the improvement in performance over the original designs. It will be noted that the final circuit breaker interrupting times are less than five cycles from 25 to 100 per cent of rating and barely exceed five cycles even for very low currents.

Conclusions

1. All objectives outlined have been attained in the development of a new 69-kv oil circuit breaker, thereby providing higher speed fault clearing, higher speed reclosing, and reduced contact and oil deterioration in reduced dimensions. Also the greater interchangeability of parts simplifies stocking of maintenance parts when several ratings are required as well as simplifying changeover when system growth demands increased interrupting capacity.

2. The dependability of this new circuit breaker under all service conditions has been verified by exhaustive tests both under controlled laboratory conditions and under actual system conditions.

3. The value of field tests with the circuit breaker operating under actual service conditions in the development of dependable high capacity circuit breakers again has been demonstrated.

Discussion

A. W. Hill (Westinghouse Electric Corporation, East Pittsburgh, Pa.): It might be inferred that the new 69-kv oil-blast circuit breaker described by the authors carries four ratings: 1,000, 1,500, 2,500, and 3,500 megavolt-amperes. The text is not clear as to the difference, if any, and since no test data are given for the 3,500-megavolt-ampere rating, the reader is prompted to inquire if it actually is contemplated in this particular structure and what interrupter would be used.

The familiar appearance of the interrupter shown in Figure 2 of the paper is embellished with arrows indicating the movement of the arc, gas, and oil, but, I believe, indicates a very inefficient use of oil since much of it flows off to one side without even coming close to the arc. Furthermore, if the arc is lengthened as indicated, by being pushed into the vent slots, an unnecessary rise in arc energy would result, which is contrary to usual design trends.

Figure 3 of the paper indicates a smooth bore for the contact adapter. This is an interesting departure from conventional threaded connections, offering closer adjustment, but possibly less security against misalignment.

In Figure 5 of the paper, it is apparent that the bushing-type current transformers are not entirely enclosed. Comments of the authors or users of this type of equipment would be appreciated, indicating to what extent this is found acceptable. This point is raised after recalling opinions of certain operators that enclosures are desirable protection.

The design of the bushing shown in Figure 6 of the paper seems to have changed without affecting the type designation and now includes solder-seal features which should add appreciably to its weather tightness. In the text of the paper, the authors say "the exposed insulation at the lower end of the bushing has a special coating to retard carbon deposition, which also seals it against moisture absorption." Some further discussion of this feature would be appreciated to bring out whether it is mechanical in action, like a glazed surface, or whether it repels carbon particles electrostatically.

At first glance, it appears that the records of field tests show somewhat longer interrupting time than do the laboratory tests, although that may be explained in part at least by the low voltage of laboratory tests at high current. The records do bring out rather forcibly that on instantaneous reclosure the second interruption is longer than the first, and they emphasize the justification for rating factors less than 100 per cent for this type of duty.

My experience with circuit breakers of this type and size, and interrupters of this general design which we have subjected to extensive laboratory and field tests, indicates that the authors have here a circuit breaker which will find quite general approval.

E. B. Rietz and C. J. Balentine: We recognize Mr. Hill's power circuit breaker experience and, therefore, are very appreciative of his conclusion that this new 69-kv circuit breaker will find quite general approval.

The circuit breakers described in this paper do not include the 3,500-megavolt-ampere rating. This higher rating would require a modification of the interrupter and larger diameter pole-unit tanks.

It would seem that practically all arrangements of baffles in the vicinity of an interrupting arc are intended to control the arc and at the same time to cool and deionize the arc as it is forced against the surface of the baffles by the oil movement. This design follows this pattern and, therefore, we cannot agree that there is inefficient use of the oil. Tests show the excellent results which are obtained.

The bushing current transformers are adequately protected against flashover within the tanks due to abnormal causes. For almost 20 years a similar arrangement has been used on 15- to 46-kv circuit breakers, and there seems to be no real justification for a complete enclosure to insure protection.

A New Line of Orthomagnetic Bushing-Type Current Transformers

JOHN W. FARR
ASSOCIATE AIEE

BUSHING-TYPE current transformers provide an ideal means of measuring current because they can be mounted around the high-voltage bushing in power circuit breakers and power transformers without taking up extra space and requiring installation work in the station. The space and installation details become increasingly important considerations in the higher voltage stations, where the usual "wound-type" current transformers are large and relatively expensive.

The use of the conventional bushing-type current transformer is considerably limited with respect to metering applications because the high potential winding consists of a single (1-turn) primary with consequent low accuracy, for the low line current designs. Therefore, practical means of providing compensation to improve the accuracy in these transformers will greatly broaden their field of application.

A method of accomplishing this was described by Boyajian and Camilli[1] in 1945. In their paper they presented data obtained from a laboratory sample. However, further refinements were required before the "orthomagnetic" current transformer could be placed in production and made available to the industry.

It is the purpose of this paper to present the general design and constructional details of a new and improved form of orthomagnetic current transformer for voltages as high as 230 kv and currents as low as 100 amperes, which now is suitable for manufacturing on a commercial basis and which are available to the industry.

A brief review of the basic principles is given, the features and some details of the new design are presented, together with an indication of the accuracy obtainable with 600-ampere multiratio designs.

With respect to the American Standards Association (ASA) accuracy classifications, the accuracy for metering applications ranges from an ASA-accuracy class rating of 0.6 B-0.5 on the 100-ampere tap and 0.6 B-2 on the 200- and 300-ampere taps, to an accuracy class rating of 0.3 B-2 on the 400- and 600-ampere taps. The ASA-accuracy for relaying application is 10L200, no different than for an uncompensated transformer.

This improved design makes it possible to obtain excellent accuracy when the lower tap of the bushing-type current transformer is used and also when it is necessary to design for a low primary current rating.

Current Transformer Error

The fundamental detail and mathematical solution of the current transformer circuit are well known. However, they will be briefly reviewed, in part, to clarify the operating principles and show how high accuracies have been obtained in the new "orthomagnetic" design through the effective reduction of its exciting current losses to low, substantially linear, quantities.

In the ideal or perfect transformer the ampere-turns of the primary winding and the secondary winding are identical, both as to magnitude and phase. On a 1-to-1 turn-ratio basis the secondary current would be equal to, and in phase with, the primary current and the transformer would have no error.

However, in the actual transformer a part of the primary current, which may be referred to as the "error-current" or more usually the "exciting-current," is required to supply its core losses and core magnetizing-current and there is a resultant error in the secondary current.

The phase position of the exciting-current also may result in a phase-position error, usually called "phase-angle" error, between the primary and secondary currents.

In the equivalent circuit and vector diagram of Figure 1, I_p is the primary current, I_s the secondary current and I_e is the error or exciting-current. The phase-angle error is indicated as θ.

The exciting-current quantity may be expressed in rms amperes and it is dependent on the secondary voltage (across the core), the number of secondary turns, also the dimensions and excitation characteristics of the transformer core.

The exciting-current may be resolved into two components: the in-phase or loss component; and the quadrature or magnetizing component. The loss component may, in turn, be resolved into two parts, the eddy current loss and the hysteresis loss. The exciting-current must be determined to calculate current transformer errors. Measurements for this purpose are more conveniently made from the secondary side because of the greater number of turns.

For the purpose of this paper the secondary voltage across the core, given as E in Figure 1(A), is the sum of the voltage drop across the external burden, the voltage drop in the leads and the voltage drop across the equivalent secondary impedance within the transformer. For a bushing-type current transformer the secondary leakage reactance is considered negligible and the resistance of the secondary

I_p = primary (line) amperes
I_s = secondary amperes
I_e = Transformer exciting amperes
E = voltage across core
$R_p + jX_p$ = primary circuit impedance (does not affect accuracy)
X_{Fe} and R_{Fe} = reactive and watt components of the core exciting current
X_B and R_B = reactive and watt components of the secondary burden (including leads and internal secondary circuit impedance)
X_C and X_L = capacitance and/or inductive that could be added to change exciting current power-factor (used in "orthomagnetic" design)
$\alpha = \phi_s - \phi_e$

where

ϕ_s = secondary burden power-factor angle
ϕ_e = transformer exciting current power-factor angle
θ = phase angle

winding is usually used as the equivalent internal secondary impedance.

For practical reasons the current transformer ratio error and phase-position (or phase-angle) error are considered in two steps and calculated separately. The ratio error is the arithmetical error current usually expressed in per cent of secondary current. The phase-angle error is the difference in phase position of the primary and secondary current, usually given in minutes.

With reference to Figure 1(B), the ratio and phase-angle errors are closely given by the following expressions when the power-factor of the secondary burden and of the transformer exciting-current are in the same order of magnitude. These are sufficiently accurate for the purpose of this paper.

$$\text{Per cent ratio error} = \frac{(I_e \cos \alpha)100}{I_s} \qquad (1)$$

$$\text{Phase angle (min)} = \frac{I_e \sin \alpha}{0.000291\, I_s} \qquad (2)$$

when α is small.

Irreducible Error in Conventional Bushing-Type Current Transformer

For a transformer with a fixed number of secondary turns and constant secondary burden impedance (Z)

$$E = I_s Z \qquad (3)$$

where

E and I_s = same as Figure 1
Z = total secondary burden impedance (internal and external, including leads)

and

$$B = \frac{22.5 \times 10^8 E}{fNCS} \qquad (4)$$

where

B = kilolines per square inch (in transformer core)
E = same as above
f = line frequency
N = transformer secondary turns
CS = square inch cross-section of core

When the primary (line) current varies the secondary current will vary, essentially, in a direct proportion because the secondary turns are fixed. Also, from equations 3 and 4, the voltage, E, and core density, B, will vary directly with the secondary current.

If the exciting current (I_e) varied in a linear relation (in direct proportion) to the core density and hence to the secondary current (I_s), it is evident from equations 1 and 2 that the errors would be constant. If this were the case, compensation could be provided in the form of turns adjustment to eliminate ratio error and exciting-current power-factor adjustment and to eliminate phase-angle error, (see Figure 1(A)—X_c and X_L).

However, in the conventional design, the exciting-current is a nonlinear function of the core density (see exciting-current curves Figure 2, curve A, for typical case) and, hence, it varies in a nonlinear relation to the secondary current. Then, in accordance with equations 1 and 2 the errors will be different for different values of secondary current.

The change in error cannot be corrected by usual means of compensation and is considered irreducible in the conventional design.

Bushing-type current transformers frequently contain taps to change the turn-ratio by changing the number of secondary turns so that rated secondary current can be obtained for different values of rated line current.

Assuming the secondary current, I_s, the total secondary burden impedance, Z, the line frequency, f, and the core cross-section, CS, to be constant, it is shown in equations 3 and 4 that the core density, B, will become greater as the secondary turns, N, becomes smaller.

Since the exciting-current, I_e, will increase as the core density becomes greater

Figure 2 (right). Orthomagnetic bushing current transformer exciting current curves. For 200-ampere rating used in 138-kv power circuit breaker

(A) Without 180-cycle excitation

B-0.1	1
B-0.2	2
B-0.5	3
B-2.0	4

and the number of secondary turns becomes smaller, it is obvious that the transformer errors will be greater as fewer secondary turns are used to obtain the standard secondary current of 5 amperes at the lower primary current ratings.

The error increase in the lower primary current designs makes the problem of error compensation increasingly difficult.

Orthomagnetic Design

The orthomagnetic current transformer makes use of the fact that when ferromagnetic material is simultaneously excited at more than one frequency, the higher frequency source of power will supply more than its proportional share of the total hysteresis losses and reactive volt-amperes required, in addition to the eddy current losses which it causes.

The proportion of loss supplied by the higher frequency becomes great when this frequency is several times the lower frequency. The lower frequency is, essentially, only required to supply the eddy current losses which it creates. Viewed from the lower frequency standpoint the core iron appears to have very high, substantially constant, permeability.

In this design the circuit is arranged so that excitation at higher than line frequency, usually 180 cycles, is supplied to the core iron from a separate source. This source, in turn, supplies most of the total exciting current required including practically all of its nonlinear components.

Then, viewed from the normal line frequency, usually 60 cycles, the transformer appears to have a very small, substantially linear, exciting current.

Exciting current characteristics with and without high frequency superimposed excitation are shown in Figure 2.

By reference to equations 1 and 2 the great advantage of this design in reducing errors is apparent.

1. The 60-cycle exciting current has been reduced to a low relative value, so that the ratio and phase-angle errors are small.

2. The remaining 60-cycle exciting current has been made, essentially, a linear function of density, so that the remaining error is nearly constant.

The small remaining error is further reduced by adjustment of the effective turn-ratio of the transformer, by use of a tapped autotransformer and the adjustment of the effective power-factor of the exciting-current, by use of a tapped capacitor and reactor combination. See Figures 1 and 5. Direct turn compensation cannot be used because in the usual design the change of a single turn would make too great a change in the transformer ratio to compensate for the small error.

Figure 4. Orthomagnetic bushing current transformer accuracy curves with adjuster settings for burden B-0.2 and remaining fixed

Standard ASA Burden	Curve Number

Error Calculations

The small errors which are realized in the orthomagnetic design are demonstrated in the following calculations.

These apply to a 200-ampere design which was prepared for a 138-kv power circuit breaker, when connected to an external secondary burden of ASA B-0.5. This transformer has 40 secondary turns with a fixed ratio of 40 to 1.

For This Case

The secondary burden ($\mathbf{Z}$) consists of the components of ASA burden B-0.5 = (0.45 + j0.218 ohm), plus the internal winding resistance of 0.0376 ohm.

Then

$$\mathbf{Z} = (0.45 + 0.0376) + j0.218 = 0.534 \angle 24.3$$

also

$I_s = 5$ amperes at 100 per cent of rated current

$f = 60$ cycle, line frequency

$N = 40$ secondary turns

$CS = 13.1$ (square-inch cross-section of core)

and

$$E = 5 \times 0.534 = 2.670 \quad \text{(from equation 3)}$$

so that

$$B = \frac{22.5 \times 10^8 \times 2.670}{60 \times 40 \times 13.1} = 1.912 \quad \text{(at 100 per cent rated current)}$$

From the exciting-current curve, Figure 2(B), which applies to this case: 1.912 kilolines per square inch density corresponds to an exciting-current

$I_e = 0.01562$ ampere

The power-factor angle of the exciting current (ϕ_e) is assumed to be made equal to the

power-factor angle of the burden current (ϕ_2) so that

$$\phi_2 = \phi_4$$

and from Figure 1 the difference angle

$$\alpha = \phi_2 - \phi_4 = 0$$

Then from equation 1

$$\text{Per cent ratio error} = \frac{0.01562 \times 1 \times 100}{5} = 0.3125$$

Since the exciting-current curve is essentially a straight line (linear) the same ratio error will exist over the range from 5 per cent to 200 per cent rated current or more. It can be reduced to a value close to zero by the tapped autotransformer, see Figure 5.

If it were required to calculate the phase-angle error it would be necessary to know the power-factor angle of the exciting-current, ϕ_2, as well as the power-factor angle of the secondary burden current, ϕ_4, so that the difference angle, α, could be determined, see Figure 1, and used in equation 2. However, the difference angle may be made closely equal to zero by means of the exciting-current power-factor adjustment, see Figures 1 and 5, so that the resultant phase-angle is essentially zero.

For cases with higher ohm burdens with the resulting higher secondary voltage drop, E, and higher core density, B, the higher range of exciting-current, I_e, may not be entirely linear and the results are not quite as good.

Measured Accuracy

Figure 3 shows typical accuracy curves at the standard ASA metering burdens taken from actual tests on the same transformer design used in the foregoing calculations. The difference between the calculated and measured errors is too small to be significant.

Figure 4 shows the variation in accuracy on this transformer when the burden is changed from B-0.2 to B-0.1 and to B-0.5 without resetting the adjustment.

General Operating Characteristics

Effect of Variation in High-Frequency Exciting Voltage

Tests show that the transformer accuracy is not critical with respect to the high-frequency 180-cycle excitation. Variations of ±10 per cent in the 180-cycle exciting voltage does not noticeably affect the accuracy. This corresponds to a variation of approximately ±5 per cent in the 3-phase 60-cycle voltage supplied to the frequency converter and used to obtain the 180-cycle power source.

Self-demagnetization

The high-frequency 180-cycle excitation serves the further purpose of keeping the transformer core essentially demagnetized. The metering accuracy will not be affected by residual magnetism from surge currents.

Effect of High-Frequency Excitation on Relay Operation and Accuracy

The orthomagnetic bushing current transformer will have, essentially, the same relay accuracy class as a conventional transformer of the same size and rating. Relay accuracy is largely a function of the saturating characteristics of the current transformer core. The high-frequency excitation has little effect on this since the core density, B_1, caused by the rated line frequency adds to the density, B_2, caused by the higher frequency to give a resultant density, B_{res}, as follows

$$B_{res} = \sqrt{B_1^2 + B_2^2} \qquad (3)$$

where

B_{res} = resultant density
B_1 = 60-cycle density
B_2 = 180-cycle density

then if

$B_1 = 100$ (assumed start of 60-cycle saturation)

$B_2 = 35$ (180-cycle density used)

$B_{res} = \sqrt{100^2 + 35^2} = 106$

It is seen that the high-frequency excitation has only increased the effective density from 100 to 106 kilolines (6 per cent).

If, for any reason, high-frequency excitation is lost the accuracy is reduced to that of a conventional bushing current transformer and the operation of protective relays (when used) is not greatly affected.

Effect of High Frequency Excitation on Temperature Rise

The core loss resulting from the high-frequency excitation will cause some additional temperature rise in the current transformer. For the usual design, the temperature rise will amount to approximately 5 degrees centigrade when the transformer is mounted in oil or 25 degrees centigrade when it is mounted in air.

Construction

The complete orthomagnetic bushing current transformer consists of the transformer itself and the compensating equipment. This equipment uses a frequency converter (or tripler) to supply the high-frequency excitation to the current transformer cores and an Adjuster Unit to set the current transformer ratio and phase angle to unity and zero respectively. A cabinet is provided in which the compensating equipment is mounted.

Figure 6 shows the arrangement of the compensating equipment in an early model. A schematic circuit diagram is shown in Figure 5.

The circuit components are described in subsequent paragraphs.

Current Transformer

The current transformer is constructed in the same general manner and has the same size as a comparable conventional bushing current transformer. The core is divided in two symmetrical parts, Figure

5, with a half of the high-frequency winding wound, in opposition, on each part and connected in series. Each half of the high-frequency winding induces an equal and opposite voltage in the low-frequency windings where they cancel. This arrangement neutralizes the mutual coupling so that there is no transfer of energy between the high-frequency exciting circuit and the low (normal) frequency secondary circuit.

The secondary winding and test winding have the same number of turns and are wound around both parts of the core in the same direction. The test winding gives a true representation of the high-voltage line current and makes it possible to test the transformer on a 1-to-1 ratio basis. It is unnecessary to use a "standard" in making accuracy tests since the secondary current can be compared directly with the primary or test-winding current.

The transformers can be made multiratio by bringing out taps in the same manner as in the conventional design. They can be assembled around bushings in power circuit breakers and power transformers in the usual manner.

Frequency Converter

The frequency converter unit consists of three small 2-winding transformers with their primary (input) windings connected in Y and their secondary (output) windings connected in broken-delta. The transformer cores are operated at a suitable flux density to generate the desired value of third harmonic energy which is taken from the delta circuit to excite the current transformer cores.

The transformer windings are provided with taps which, together with a loading rheostat and tapped capacitor, are used for the high-frequency load power-factor and voltage adjustment.

This converter contains no moving parts such as rotors or commutators and is free from mechanical wear.

The converter components are mounted on a panel and provided with selector switches for adjustment. A single converter unit will supply sufficient energy to excite a complete 3-phase bank of current transformers.

Adjuster Unit

The adjuster unit consists of a tapped autotransformer for ratio adjustment and a tapped capacitor and reactor for phase angle adjustment. These components are mounted on a panel and provided with selector switches.

Figure 6. Compensating equipment for orthomagnetic bushing current transformer

Table I

Circuit Voltage	Maximum Primary Amperes
115 kv	600
138 kv	600
161 kv	600
230 kv	600

Tap Ratios, Amperes	Metering Accuracy Classes
100 to 5	0.6 B0.1, 0.6 B0.2, 0.6 B0.5
200 to 5	0.3 B0.1, 0.3 B0.2, 0.3 B0.5, 0.6B2
300 to 5	0.3 B0.1, 0.3 B0.2, 0.3 B0.5, 0.6B2
400 to 5	0.3 B0.1, 0.3 B0.2, 0.3 B0.5, 0.3B2
600 to 5	0.3 B0.1, 0.3 B0.2, 0.3 B0.5, 0.3B2

Cabinet

In the standard set of equipment a steel outdoor cabinet is provided with mounting space for one frequency converter unit and three adjuster units. This set of components will supply compensation for a bank of three current transformers.

Application

The orthomagnetic current transformer is particularly suited for use in the higher voltage circuits with line current ratings down to 100 amperes. They may be used with all the usual arrangements of meters and relays in the same manner as the regular wound type current transformer.

Standard Ratings and Metering Accuracy

Standard multiratio orthomagnetic bushing-type current transformers are being made available for the circuit voltages, current ratios, and accuracy classes indicated in Table I.

Relay Accuracy

These transformers will have a minimum relay accuracy of (ASA) 10L200 on the full winding (600-5 ampere tap).

Typical Input Power Requirements

Typical input power requirements for compensating equipment for bank of 3 138-kv bushing current transformers:

Input from supply circuit is 1.5 kva at 28 per cent power factor (420 watts) 3 phase, 60 cycles, 120/208Y.

Output to excite bushing current transformers cores is 250 volt-amperes at 80 per cent power factor (200 watts) 1 phase, 180 cycle, 120 volts.

Summary

The development of this new line of orthomagnetic bushing-type current transformers makes it possible to obtain the higher classes of metering accuracy, in the lower range of line current ratings, in high-voltage systems. At the same time it is possible to retain the advantage of minimum space, easy installation, dependable operation, and much of the economy of the usual bushing-type current transformer.

The multiratio feature incorporated in the design of these transformers will materially facilitate their application on circuits where load conditions may change.

A Survey of Bushing-Type Current Transformers for Metering Purposes

G. CAMILLI
FELLOW AIEE

Synopsis: The great simplicity, reliability, and low cost of bushing-type current transformer has led inventors to devise various schemes to improve its accuracy to metering standards. This paper reviews these schemes, culminating in the orthomagnetic device described in detail in a paper by J. W. Farr.[10]

INVENTORS in the instrument transformer field have been intrigued for many years by the bushing-type current transformer, as may be gathered from the 160-item current transformer bibliography given at the end of this paper. The bushing-type current transformer is a device with exceptional simplicity, convenience, reliability, adaptability to the highest voltages (present and future) and economy, and yet it has been disappointing in not being so adaptable to the smaller line currents. For line currents under 1,000 amperes, its accuracy diminishes with diminishing current. The story of the development of this type of a current transformer is therefore that of attempts at improving its accuracy to make it suitable for metering at the smaller line currents.

Impressing voltage on a transformer brings into play an exciting current, and drawing current from the transformer brings into play an impedance voltage. In a current transformer, the impedance voltage may be ignored, but not the exciting current because it affects the current ratio. Operating at a reasonable flux density, a transformer requires a certain number of ampere-turns, so that the more the turns the less the current will be. As the bushing-type current transformer, built around the bushing conductor as its primary, has only one turn its exciting current has to be larger than that of units with many turns. If this were the only problem, the challenge of the bushing current transformer would not have been half as difficult as it actually has been.

The exciting current varies nonlinearly with the load and thus resists simple corrective measures such as compensation by modification of turn ratio.

The object of this paper is to review briefly the various schemes that have been proposed or used to overcome these difficulties. While most of these schemes are applicable to both the wound-type and the bushing-type current transformers, emphasis will be placed on the latter.

Analysis of the Problem

Before discussing the several different arrangements that have been used for increasing the accuracy of current transformers in general, and of bushing-type current transformers in particular, it is worthwhile reviewing the nature of the problem involved in this discussion. All current transformer performance characteristics are given by curves of ratio and phase angle since these vary in value as the primary current varies from full load to fractional loads. It may be appreciated on reflection that the magnitude of a ratio correction factor would be of little or no consequence if it were constant from full load to, say, 10 per cent of full load, since any multiplier would be easily applied to a watthour meter reading. But, if the correction factor is not the same at all loads, doubt can arise as to what multiplying factor is to be applied to the monthly total of the watthour meter.

The case of phase angle also is troublesome because even if the angle of phase shift were constant, the ultimate correction would differ for different power factors, and power factors are normally different at different loads.

The problem, therefore, is to make the ratio error at least constant (if not smaller) and the phase angle smaller (if not constant). The ratio and phase angle vary with load because the exciting current is not proportional to the load. If they were constant the current transformer would have a single ratio correction and single-phase angle correction at all currents.

Since current transformers are operated at low densities the deviation of the excitation curve from a straight line is not due to saturation but by just the opposite, that is, the increase in permeability with increasing density around the lower bend of the magnetization curve, see Figure 1.

The results of this nonlinearity are almost as objectionable as those of saturation with the difference that the errors are larger at the smaller loads instead of at the higher loads.

In the final analysis, however, the errors of a current transformer are dependent

Figure 2. Permeability of core materials at low flux density

upon the phase angle and magnitude of its exciting current, and the smaller this current the smaller are the resultant errors.

Corrective Schemes

Various schemes proposed for improving the accuracy of current transformers can be grouped under the following classifications:

1. Direct reduction of the exciting current I_0.

2. Two-stage transformation. Without modification of the exciting current I_0, an attempt is made to modify the secondary current by a quantity equal to the exciting current.

3. Rotation of the exciting current vector. The phase angle is reduced by producing a rotation of the exciting current I_0 and subsequently the ratio error is modified by other schemes.

4. Straightening the exciting current curve.

5. Straightening of the exciting curve and simultaneous reduction of the exciting current.

Figure 3. Effect of capacitor shunted across tertiary winding and of burden power factor

Solid lines: No compensation
Dashed lines: Capacitor across tertiary winding

Direct Reduction of the Exciting Current

A reduction of the exciting current can be accomplished by an increase in core weight as well as in the number of primary turns. The latter corrective measure, of course, does not apply to bushing-type current transformers where the primary ampere-turns equal the primary current. To produce a high-voltage current transformer with negligible errors, using ordinary silicon steel, the core would have to be increased to prohibitive dimensions.

Current transformers are operated at very low flux densities (100 to 5,000 lines per square inch) and, therefore, in order to reduce I_0 a material is desired which has low losses and high permeability at low inductions. Such materials are now available[47] and are known in the trade under such names as Nicaloi, Hypernik, Permalloy, and Mumetal. These nickel-iron alloys, especially the permalloys (78.5 per cent nickel, 21.5 per cent iron), have several times the permeability of the silicon steels (see Figure 2) and would be very useful in the construction of bushing-type current transformers except for some disadvantages which limit their use to special applications only.

The good qualities of these alloys depend on the purity of their ingredients and to a larger extent on the accuracy of manufacture. The cost of these materials is several times that of ordinary steel; their saturation densities are low and they have very poor resistance to mechanical shocks.

Mumetal (77 per cent nickel, 5 per cent copper, 16 per cent iron, 2 per cent manganese) is less sensitive to mechanical stresses and shocks than Permalloy. With such materials it is possible to obtain bushing-type current transformers having fairly good accuracy at a rated primary current 500 amperes and higher. For lower currents more complicated additional schemes must be used.

For the purpose of reducing the wattless component of the exciting current, the current transformer could be loaded with an additional capacitive burden.[121, 32, 49] For this purpose it would be sufficient to add a capacitor in parallel with the normal burden. An extremely large capacitor would be required to produce an appreciable effect because the voltage across the secondary of the current transformer is normally only a few volts. This difficulty can be overcome by providing the transformer with a tertiary winding with many turns to which is connected a relatively small size capacitor. For a constant useful burden, and a

Figure 4. Incremental permeability of silicon steel

fixed primary current, the compensation of the wattless component of the exciting current can be complete. In general, by this scheme, it is possible to obtain similar errors at a primary current of 600 amperes as would be obtained at 1,000 amperes without the use of the capacitor (see Figure 3). This scheme has a very important drawback. Under overloads or during an accidental open-circuit condition the voltage induced in the tertiary winding will be extremely high which may result in the failure of the capacitor. This failure may or may not be detected. The capacitor could be protected by a gap but this is added complication. This type of compensation has received very little or no support by the industry.

Bushing-Type Current Transformers with Supplemental Constant Excitation at Normal Frequency

As has been stated before, current transformers, in general, are operated at very low alternating flux densities so as to reduce their exciting current, but a benefit proportional to the reduction in density is not realized because at such low densities the permeability of the core also is greatly reduced.

Referring to Figure 4 it will be seen that the permeability (incremental or instantaneous permeability) of a representative sample varies 10-to-1 in the range of

Figure 5. Auxiliary excitation scheme of Illovici

Figure 6. Sixty-cycle excitation required for silicon steel which is pre-excited at 60 cycles to 10 kilolines per square inch

densities from 0 to 16 kilolines per square inch.

Although the 60-cycle component of the exciting current is not a direct function of this permeability but a complicated function of the curve of permeability for the range of the a-c flux density, yet the incremental permeability is used here as a convenient magnifying lens or index.

A bushing-type current transformer is likely to operate at 500 lines per square inch, a zone in which the permeability is one-sixteenth of that at 16 kilolines per square inch. If a current transformer could be operated with a low alternating flux density (say, 500 lines per square inch as before) but at the highest permeability of iron, then some real benefit could be gained.

Figure 7. Characteristics of transformer of Figure 5 with constant voltage excitation for different line power factors

Connection: 200 amperes
Burden: 60 volt-amperes at 1.0 power factor
Differential excitation: 70 volts

Ilovici[35,36,37] accomplished this by magnetizing the core to maximum permeability by an independent source of power.

In its simplest construction the core is split up into equal parts, half of the turns of the auxiliary exciting winding are wound around the first core part, the other half is wired in opposite direction around the second core part. The secondary winding is wired around the total core in the usual manner (see Figure 5). With this arrangement the mutual inductance between the auxiliary circuit and the other windings is eliminated.

The scheme requires a source of constant voltage. One of the advantages of the scheme is the facility with which the performance characteristics of the current transformer can be predetermined. This can be simply done with the help of data as shown in Figure 6. The disadvantages of the scheme are:

1. When the auxiliary voltage is obtained from the same power circuit to which the current transformer is connected, the performance of the current transformer is dependent upon the power factor of the load to be measured.

2. The performance of the current transformer is influenced by the voltage variations in the supplemental excitation.

The change in the characteristics brought about by the changes in the power factor of the circuit to which current transformer is connected, can be seen from the curves of Figure 7.

That the performance of this type of current transformer is affected by the variations in the voltage applied to the auxiliary exciting winding, can be seen from Figure 8.

Self-Excited Current Transformers

The excitation necessary to improve the accuracy of bushing-type current transformers can be provided by the following three methods:

Self-Excitation Through a Tertiary Winding Connected Across an Auxiliary Burden

This scheme is shown in Figure 9.

The core is divided in two equal portions; auxiliary windings are wound on each core section and are connected as shown in the diagram with the two free terminals connected across an auxiliary burden.

With this scheme good accuracy can be obtained for any one value of secondary current but not throughout the ordinary range of secondary currents, see Figure 10.

Figure 8. Effect of differential excitation voltage on transformer of Figure 5

Burden: 6.0 volt-amperes at 1.0 power factor
Load condition: 1.0 power factor
Connection: 100 amperes

Auxiliary Excitation Can be Obtained from an Auxiliary Core as Shown in Figure 11

The main core[14] is split into two portions, each portion being magnetized in the opposite direction by a winding energized from an auxiliary core.

The two portions of the core being magnetized in the opposite sense there is no resultant effect on the secondary winding if the two portions are equal, as the induced electromotive forces in any winding which embraces both portions will cancel out. Actually, however, it is sometimes convenient to arrange for the two portions to be slightly unequal as this then has the same effect as keeping proportions equal and retaining the ratio compensation by some of the secondary turns embracing the auxiliary core.

By this scheme the phase angle can be reduced to roughly one-half of the figures normally obtained by the use of silicon steel cores, Figure 12. Furthermore, the phase relationship which exists between the cross flux and the main flux is such that an improvement can be obtained when the secondary burden becomes reactive. This automatically compensates for the greater ratio error which otherwise exists when the burden becomes reactive.

From the test results shown in Figure 12 it is evident that while this scheme is beneficial it does not give the complete answer to our problem and some additional method should be used.

69-kv bushing-type current transformer
Primary amperes: 65
Burden: 16 volt-amperes at 1.0 power factor
Auxiliary burden: $R=0.040$ ohms
$X_c=14.75$ ohms
Solid line: no additional excitation
Dashed line: excitation from auxiliary burden

Excitation by Charging Current

Bushing-type current transformers can be improved by separate excitation with a current substantially in quadrature with the normal working current. The latter can be furnished by a capacitor-type bushing as shown in Figure 13.

Calculations and test results show that with certain limitations the scheme is feasible. Small changes in the phase of the compensating current do not seriously affect the phase angle and ratio but a large change greatly alters the characteristics. A change of burden entirely changes the amount of compensation required.

The Effect of D-C Excitation of the Core on the Characteristics of a Current Transformer

From Figure 4 it will be seen that the maximum incremental permeability of the iron ordinarily used in current transformers occurs at approximately 16,000 lines per square inch. It might appear that if a mean density of approximately this value is maintained in the core by d-c excitation and the desired a-c flux superposed on it, the permeability will be at the maximum value and practically constant over the entire cycle. Hysteresis and the eddy currents, of course, take their toll from the alternating flux so that the permeability realized for the alternating flux will not be as good as judged by a d-c magnetization curve, but still it may be expected that the permeability in the zone of high flux density would be far better than at the beginning of the saturation curve. If no further provision is made other than direct current, however, the hysteresis loss will be higher at the higher mean density than at the original, the eddy currents remaining unchanged. In general, the a-c excitation for a given alternating flux density is increased by superposed d-c excitation.[107] Thus, Figure 14 gives the core loss and exciting current obtained on annular ribbon wound core, while Figure 15 gives the results obtained on a current transformer when it was tested with and without additional d-c excitation.

The A.E.G.* Transformer[99,109,110]

Instead of using an auxiliary core to furnish a current for the premagnetization of the working core of the current transformer, the auxiliary magnetizing current can be derived directly from the secondary current of the current transformer, Figure 16(A).

The flux in each core is due to the result of the primary and secondary ampere turns. By the proper selection of the direction of winding and of the number of turns of the auxiliary windings in core 1, the ampere turns of the primary can be made to exceed those of the secondary, while in core 2 the secondary ampere turns can be made to exceed those of the primary. In other words, for core 1

$$NI_1=(N_s-M_2)I_2$$

and for core 2:

$$NI_1=(N_s+M_2)I_2$$

The connections shown in Figure 16(B) are equivalent to those of Figure 16(A), in which

$$N_s-M_2=N_1$$

$$N_s+M_2=N_2$$

Figure 17(A) shows the vector diagram of the ampere turns of a normal current transformer. Figure 17(B) shows the diagram of the ampere turns of core 1 of our premagnetized current transformer.

Figure 11. Additional excitation from auxiliary core

Figure 12. Characteristics obtained by excitation from auxiliary core

Main cores: 16 inches inside diameter by 21 inches outside diameter by $3^1/_8$ inches
Auxiliary core: 16 inches inside diameter by 21 inches outside diameter by $1^1/_4$ inches
Connection: 1-turn primary
40-turn secondary
4 compensating turns on each core
Burden A: 19 volt-amperes at 0.89 power factor
Burden B: 6 volt-amperes at 1.0 power factor
Solid lines: uncompensated
Dashed lines: compensated

In this core the primary ampere turns exceed those of the secondary, and the resultant ampere turns I_1W_1 are

$$I_1N+I_2N_1=I_1W_1$$

It should be noted that the resultant ampere turns in this core are approximately in phase with the primary ampere turns. Likewise Figure 17(C) represents the diagram of the ampere turns of core 2. In this core the secondary ampere turns exceed those of the primary, and the resultant ampere turns I_2W_2 are approximately in phase with the secondary ampere turns according to the equation

$$I_1N+I_2N_2=I_2W_2$$

For a given burden the induced voltage E_2 determines the value of the common flux ϕ in the two cores and the no-load ampere turns I_1N of the current transformer. The foregoing no-load ampere turns are the result of the two ampere turns I_1W_1 and I_2W_2. The two ampere turns I_1W_1 and I_2W_2 are almost in phase opposition, hence each must exceed the no-load ampere turns of the current transformer. As a result the flux density in the two cores is increased to the region of maxi-

Burden: 6 volt-amperes at 1.0 power factor

mum permeability. It follows that the exciting current is greatly reduced because it is the resultant of two components which not only are fairly small in value but also are almost in phase opposition. Due to the fact that in one of the cores the magnetization is proportioned somewhat higher than that of maximum permeability, and in that of the second core somewhat lower than maximum permeability, it follows that satisfactory operation of the transformer is obtained throughout the working range of the current transformer.

These theoretical considerations have been limited to two cores. However, the wound-core construction permits the same results to be obtained with a single core by placing some of the turns between the layers of the core spiral.

Typical results obtainable from this type of compensation are shown in Figure 18.

Two-Stage Current Transformers[34]

The Brooks 2-stage transformer is one of the most fundamental and most effective means for the reduction of transformer errors. It automatically corrects ratio and phase-angle errors caused by changes in primary or secondary current.

This current transformer has two toroidal cores, Figure 19(A). The first core has an ordinary secondary winding and when taken by itself would yield a current with errors identical to those in the ordinary silicon iron transformer. Both primary and secondary current pass through respective windings of the second transformer, the ratio of turns is approximately equal to the desired ratio of the primary to secondary current. On the second core the secondary and primary ampere turns are in opposition. This core has another winding N_3 called the auxiliary or tertiary winding, having approximately the same number of turns as the secondary winding.

Referring to Figure 19(B) the primary current I_1 of the first stage will be equal to the secondary current I_2 plus the exciting current I_{e1}. I_{e1} also represents the primary current of the second stage transformer, and is thus equal to the vector sum of the tertiary current I_3 plus the exciting current I_{e2} of the second stage. If the exciting current I_{e2} is small compared to I_{e1} then the vector I_{1R} will very closely approximate I_1.

Figure 17. Ampere-turns diagrams for excitation scheme of Figure 16(B)

Figure 18. Characteristics of transformer of Figure 16(B)

Cores: Silicon steel 16¹/₄ inches inside diameter by 18¹/₂ inches outside diameter by 4 inches
Burden: 12.5 volt-amperes at 0.9 power factor
Connection: 300 amperes

The current I_3 circulating in the tertiary winding acts on an auxiliary current coil of a special wattmeter. If I_3 were equal (vectorially) to I_{e1} the correction would be perfect and the errors would always be zero. This would be true if the impedance of the tertiary circuit was zero. In practice, of course, the tertiary circuit has impedance which necessitates flux in the second core. This flux requires an exciting current I_{e2} which is the cause of the residual error.

Figure 19(A). Diagram of 2-stage current transformer

Figure 19(B). Vector relations of 2-stage current transformer

To reduce the residual current I_{e2} still further, in many cases the second core is made of special high permeability material (Permalloy).

Figure 20 shows results typical with this scheme and with a single stage current transformer of the same rating.

The 2-stage transformer has the disadvantage of requiring special 2-stage watthour meters and instruments. The circuit can be modified to permit the use of standard meters.[14] The current transformer is identical to the original 2-stage unit except that the tertiary current I_3 is brought to the terminals of the burden Z in such a manner that it adds (vectorially) to the current I_3.

Connecting directly to the tertiary winding would not accomplish this result. If we neglect, for the sake of simplicity, the impedance of the windings which we assume to be of equal turns, then the voltage ZI_3 produced by the current I_3 is equal to electromotive force E_3 due to the flux ϕ_e in the first core. The voltage existing at the terminals of the tertiary winding before it is connected to the burden Z also is equal to E_3 because the flux in the second core (when the tertiary winding is open) also is equal to ϕ_e. Therefore, the connection of the tertiary winding directly across the terminals of the main burden will not cause it to draw any current from the tertiary winding.

To draw a current from the tertiary

Figure 20. Characteristics of 2-stage current transformers of Figures 19(A) and 21

Burden: $Z = 40$ volt-amperes, 0.996 power factor
$Z' = 6.2$ volt-amperes, 0.80 power factor

winding it is necessary to produce a voltage drop in the tertiary circuit equal and opposite that produced across the burden by the secondary current I_3. This can be done by inserting an impedance Z' equal to the compensated burden in the tertiary circuit and by forcing through it a current equal and opposite to I_3. The latter is supplied by a 1-to-1 ratio transformer connected in the main circuit of the transformer. The complete scheme of connection is shown in Figure 21. The net mutual impedance between the secondary and tertiary winding is brought to zero and although the two circuits have a common connection (across the burden) they act as though they were completely independent and do not influence each other.

Figure 21. Scheme for using single element meter with 2-stage transformer

Figure 22. Equivalent circuit and vector diagram for 1-to-1 transformer

Figure 21 illustrates the connection of such a current transformer arrangement with a number of instruments. Since great precision is necessary only in the meters and not in the relay coils and in the indicating instruments, only the watthour meter is shown included in the second stage. This leads to greater accuracy by reducing the burden and exciting current of the second stage. In such applications the compensating impedance Z' obviously represents the impedance of only that portion of the total burden that must be corrected.

The addition of a dummy burden results in a total burden approximately twice that used with a simple metering transformer. The errors of this transformer at a given burden are thus approximately equivalent to those of the original Brooks transformer operated at twice that burden. It is one of the fundamental requirements of all 2-stage transformers that the exciting current of the first stage be small when compared with I_2 and the exciting current of the second stage be small with respect to I_3. This condition is fulfilled for relatively high ratio transformers as well as low ratio transformers with very low burdens. Very satisfactory results can be obtained for these cases, see Figure 20.

Systems Based on the Rotation of the Exciting Current Vector I_e

Before reviewing compensation methods based on rotation of the exciting current vector I_e, it is desirable to discuss the modified current diagram proposed by Mollinger.[21]

The theory of a current transformer can

Figure 23. Error diagram

best be illustrated by the usual equivalent circuit diagram shown in Figure 22(A), and the vector representation of the currents and voltages shown in Figure 22(B).

By using the Mollinger diagram phase-angle errors (β) and ratio errors (δ) are obtained directly by projecting the exciting current I_e on the X and Y axes, see Figure 23. With a variable load the terminus of the vector I_e moves along a straight line the slope of which depends on the power factor of the burden.

Figure 23 shows that a rotation of the vector I_e (from I_e to I_e') would produce a reduction of the phase angle β and an increase of the ratio error δ.

The increased slope of Mollinger's line under this condition shows that the range of ratio errors for variable load has been increased also.

In the "Wilson" transformer[55] the number of secondary turns is changed automatically with the load and the ratio error is maintained approximately constant. In this type of transformer a portion of the secondary turns is wound through small holes as shown in Figure 24.

Figure 24. Wilson's transformer

Table I. Data for High Accuracy 115-Kv Bushing-Type Current Transformer, 400-5

Internal Diameter 17¼ Inches; Weight 270 Pounds; Burden 50 Volt-Amperes at 50 Per Cent Power Factor

0.5	1.0006	−11
1.0	1.0001	−7
2.0	1.0007	0
3.0	1.0004	+1
4.0	1.0000	0
5.0	0.9999	+1

Short-circuited turns also embrace a portion of the core S_1. The currents which circulate in the auxiliary turns and in short-circuited turns produce a decrease and a rotation of the flux which links the section S_1. This rotation reduces the phase angle error because the flux in S_1 induces an electromotive force in the auxiliary turns which lags the output electromotive force. Since the output electromotive force is fixed by the loading and by the burden it follows that the resultant flux and the exciting current are rotated in the direction of producing a reduction in the phase angle. The auxiliary windings also have the effect of increasing the flux density in S_2 and of decreasing the flux density in S_1 with the net result that the material will be working in two different regions of the magnetization curve. By the proper selection of the number of auxiliary turns and the relative cross sections of S_1 and S_2, it is possible to flatten the ratio error curve.

This scheme has been very successfully applied to wound-type current transformers and with limited results to bushing-type current transformers.

Wellings and Mayo Current Transformer[74]

This transformer consists of a main core "A" and an auxiliary core "B" which are assembled on the primary conductor, see Figure 25. The first core of relatively

Figure 25. Wellings and Mayo's current transformer

Figure 26. Vector diagrams of Wellings and Mayo's current transformer

large cross section has a secondary winding n_2. The second core "B" of small cross section has a winding n_3' which is connected through a resistance "R" to a winding n_3 wound on the main core "A." In this auxiliary circuit will circulate a current I_3 the flux of which in the main core will combine with that produced by the primary current I_1. The resultant ampere turns of the exciting current is due to vectorial sum of the primary, secondary, and auxiliary ampere turns.

Figure 26(A) is the vector diagram of a single core current transformer considered on a 1-to-1 basis. The exciting current I_e is the vector sum of I_1 and I_2. Figure 26(B) is the diagram for the auxiliary core. If the two diagrams are combined so that the common vectors I_1 of Figures 26(A) and 26(B) coincide, the vector diagram of the combination can be drawn. Figure 26(C) shows how vector I_3 combines with vector I_1 giving a net primary current I_1' with an exciting cur-

Figure 27. Modified Wellings and Mayo scheme. Additional magnetization from auxiliary core plus compensation by method of Wellings and Mayo

Figure 28. Characteristics of modified Wellings and Mayo current transformer of Figure 27

Primary current: 200 amperes
Burden: 19.2 volt-amperes, 0.89 power factor
Main cores: 16 inches inside diameter by 21 inches outside diameter by $3^1/_8$ inches
Auxiliary core: 16 inches inside diameter by 21 inches outside diameter by $1^1/_4$ inches

rent I_e' which is the vector sum of I_1' and I_2. The net result is a reduction in phase angle and increase in ratio I_1/I_2. A few turns of the secondary current are wound on the auxiliary core to compensate for the ratio error, see Figure 25. The effect is to rotate the exciting current vector to I_e'', Figure 26(D), which gives further reduction in phase angle as well as a reduction in ratio.

With this scheme reasonably good results have been obtained in bushing-type current transformers when the rated primary current is not lower than 600 amperes. This limiting value of course applies to high-voltage current transformers. Better results have been obtained with the scheme just described if it is combined with that shown in Figure 11. This combination is shown in Figure 27, and the comparative results with and without compensation are shown in Figure 28.

Figure 29. Pfiffner's transformer

Figure 30. Reactor with adjustable core

Figure 31. Connection diagram of current transformer compensating scheme using reactor similar to Figure 30

Straightening of the Exciting Current Curve

The exciting current is the source of both ratio and phase angle errors, and any scheme that makes exciting current linearly proportional to primary current will make both these errors constant. Once made constant their magnitude can be reduced by several different methods.

A general principle which has been used is to balance increasing and decreasing permeability against each other.

One method of accomplishing this is to combine the separate exciting currents of separate cores, one saturated, the other operated at low densities. This result may be obtained in a single unit if the core of the current transformer is so constructed that one section or length of the core operates saturated, another at very low density, resulting in a straight line volt-ampere curve for the whole core. The proper execution of this requires that the magnetic circuit does not have the same cross section along its entire length but be reduced in one or more places. E. Pfiffner[88] did this by slotting the main core to produce high saturation at section X, Figure 29. The capacitor and the reactor shown in the figure neutralize the exciting current which is rendered approximately linear by the restriction of the core. According to published results this method reduces the errors only by about 50 per cent.

Schwager and Treat[111] obtained much better accuracies by connecting a special reactor across the burden, see Figure 30. In this scheme the transformer core has uniform cross section and the shunt reactor has sections working at different degrees of saturation. After the straightening of the exciting current has been accomplished, the errors are compensated by the addition of capacitors and resistances as shown in Figure 31.

With this scheme the errors at all loads are equalized by increasing the errors at those points where they would otherwise be low. At best the magnetization curve can be straightened at the expense of increasing the actual value of the magnetizing current as is shown in curve "B" of Figure 1.

The capacitor is connected to a tertiary winding having a large number of turns to reduce its size. Under large overload conditions the voltage across the capacitor can assume large values which may result in its failure.

This type of transformer is very sensi-

tive to changes in the secondary burden. A change in the burden would involve the readjustment of the secondary reactor. To avoid having to return the transformer to the factory when it is necessary to make changes in the burden, each individual transformer and its reactor are adjusted at the factory for a maximum permissible burden specified by the manufacturer. The difference between the actual secondary burden and the adjusted burden is made up by a replaceable burden furnished by the manufacturer. Fairly good accuracies have been obtained with this scheme at a primary current as low as 300 amperes.

The data shown in Table I refer to a 400-ampere 115-kv bushing-type current transformer.

Straightening of the Exciting Curve and Simultaneous Reduction of the Exciting Current

The principle of operation of these transformers[57,158,153] is as follows:

If a core is excited from an a-c source and then a higher frequency excitation superimposed on it through a separate winding of suitable design, maintaining the original excitation unchanged, it will be observed that the volt-ampere input by the original (lower frequency) circuit is diminished by the superimposition although the total losses in the core may be considerably increased. To the lower-frequency source, the iron behaves as an improved material: reduction of the exciting current to less than 50 per cent of its original value, without high-frequency superimposition, has been obtained, see Figure 32. A much more important result of auxiliary high-frequency excitation is it makes the low-frequency exciting current proportional to the primary current. By the superimposition of the additional high-frequency excitation ratio errors are divided by more than ten, and phase angle errors by more than 60. With the errors rendered constant the phase-angle error is compensated for by an auxiliary impedance *Z* and the ratio error by the tapped autotransformer between the secondary and burden, Figure 33. Excellent accuracies can be obtained by this scheme. The ratio and phase-angle characteristics of two low ratio current transformers, one for 69 kv and the other for 161 kv, are exhibited in Tables II and III.

Other details in the performance characteristics and in construction are given in the paper by J. W. Farr.[149]

Conclusions

Much progress has been made in the design of bushing-type current transformers. In spite of this progress the wound-type transformer will maintain a limited field of application. It will fill the gap for the lowest ratios such as 5/5 to 100/5 and also will be used in all those cases where insensitivity to fairly large burden variation is imperative.

The latest bushing current transformers and in particular the orthomagnetic type could replace the wound-type current transformers of ratios 100/5 and higher. Compactness, convenience, facility of maintenance, and economy are the factors which will in many cases have decisive factors in favor of the bushing type.

The Theory of the Current Transductor and Its Application in the Aluminum Industry

T. R. SPECHT
ASSOCIATE AIEE

R. N. WAGNER
ASSOCIATE AIEE

THE current transductor is one of the great family of apparatus known variously as magnetic amplifiers, saturable core reactors, or transductors. These devices are a-c inductors, whose effective inductance can be changed by superimposing a d-c magnetomotive force. The current transductor is a transductor specially designed and calibrated so that the alternating current flowing in the a-c circuit is a direct measure of the direct current flowing in the d-c circuit. It is meant to be used for the measurement of the direct current.

The current transductor in comparison with the conventional d-c ammeter shunt commonly used in d-c power circuits has two outstanding advantages:

1. Insulation of the secondary circuit from the measured source. With the d-c shunt, the voltage of the main circuit appears at the instruments on the switchboard. With the transductor, the secondary circuit is fully insulated and may be grounded. The importance of isolation of the main or primary circuit is well understood in a-c practice. Isolation prevents damage to the primary circuit from any possible grounds in the secondary circuit. Insulation prevents damage to any of the instruments or injury to any of the operating personnel. It permits instruments to be installed at any convenient location without regard to primary voltage. To realize the full benefit of this advantage, the secondary circuit of the transductor should of course be grounded.

2. Convenience and economy in use of any number of instruments. With the d-c shunt, the value of the lead resistance to the meters is critical, and in the lower current ratings the number of meters that can be connected to one shunt is limited. As the current transductor has characteristics similar to the regular a-c transformer, the resistance of the meter or leads is not critical. The current transductor can be designed to carry as many meters as is desired, even in the low current range. In addition to his freedom to add additional instruments, relays, or other current operated devices as he may desire, the operator has the choice of all the wide range of a-c devices to be used in the secondary a-c circuit of the current transductor.

Connections for Current Transductors

A current transductor resembles, physically, a double-secondary a-c transformer. For purposes of analysis, the current transductor may be visualized most easily by thinking of it as two conventional a-c transformers with their primaries connected in series. See Figure 1. The secondary windings may be connected in series or in parallel as is shown in the figure, but in both cases one of the secondary windings must be connected in reverse polarity to that of the other winding. The secondary windings are then excited from a source of alternating voltage and an ammeter or other burden is put in the a-c line. For purposes of this analysis, it is assumed that the voltage drop across this burden (the ammeter) is small compared to the source voltage.

Application in the Aluminum Industry

It is customary in aluminum reduction plants to operate several d-c machines in parallel on a common bus to produce the relatively large amounts of current required for aluminum production. The central switchboard from which these machines are operated usually contains for each machine a millivoltmeter operated from a shunt in the d-c leads and calibrated in machine amperes. The leads from these shunts are often long and may require special meter calibration. The leads operate at bus voltage and are difficult to protect satisfactorily by fuses or other devices. Therefore, they produce electrical hazard in the switchboard and some fires have resulted.

In the hope of eliminating some of theses disadvantages, a new aluminum reduction plant has been equipped recently with 120 transductors rated 2,000 amperes direct current to 1 ampere alternating current. These transductors were made with the a-c coils in series. This unit is shown in Figure 12. These are in the d-c machine leads and each operates two a-c ammeters in series. One is located near each machine and the other is located several hundred feet distant at a central control switchboard. At this switchboard is located a 110-volt 60-cycle source large enough in capacity to supply 40 transductors. One side of this source is common to all the instruments and the other is run as a bus the length of the station and connecting to each transductor. With this circuit arrangement, it can be seen that only one wire is required from each machine to the central board for load indication. This lead is only at 110 volts and can be adequately fused. Especially calibrated dials were used on the instruments which were made from test curves on the first transductor. All transductors and all instruments are alike. The transductor is constructed similar to a current transformer and should be stable over a number of years.

A second application in the aluminum

Paper 50-64, recommended by the AIEE Instruments and Measurements, and Transformers Committees and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30-February 3, 1950. Manuscript submitted November 1, 1949; made available for printing December 2, 1949.

Figure 1. Connections for current transductors

industry is in the main d-c circuit to the cell lines. Here it is required to measure currents often as high as 50,000 amperes with the greatest possible accuracy. The shunts for these circuits are mammoth devices weighing several hundred pounds. Their resistance is so low that it requires very special equipment to calibrate them to the required accuracy. The millivolt output must be kept low or the power consumption and heating will be prohibitive. This latter objection makes it difficult to provide the necessary instruments at remote locations required by the operating personnel. In some cases it has been necessary to use shunt leads as large as 500,000 circular mils to operate meters at the distances required.

With these objections in mind, the cell line circuits in the plant are being equipped with transductors nominally rated 75,000 amperes direct current to 37.5 amperes alternating current. These units also had the a-c coils connected in series. This transductor as installed is shown in Figure 18, and during factory test in Figure 9. The switchboard instruments in this case are 5-ampere iron vane instruments specially calibrated and operated from a current transformer in the 37.5-ampere 440-volt exciting circuit. Several remote indicating and recording instruments are used which constitute a circuit some 3,000 feet long.

The ability to insulate instrument circuits is very important. The ease of installation of the transductor, the wide choice of instruments available, and the possibility of locating these instruments at any point without thought to lead length are further important advantages. The 16.5 kva of exciting power may be considered a disadvantage, however, the actual watts in excitation are below 1,000 and are less than in a large shunt.

Graphical Solution for Series Connection

The alternating current flowing in the secondary can be determined by the following graphical method. Referring to Figure 2, the change in the flux linkages linking the a-c secondary coil of unit Number 2 is plotted as a function of the secondary current for a particular value of direct current in the primary winding. It is assumed in this analysis and throughout this paper that there is no leakage flux from the cores; that is, that in a given core and a given instant of time, the flux density is the same throughout the core. The effect of the return conductor is discussed more fully later in this paper. Referring again to Figure 2, the zero point for the flux linkages is the value of flux linkages due only to the direct current with no alternating current flowing. In Figure 3, the curve from Figure 2 is replotted for unit Number 2, and also the similar curve for unit Number 1. Since the two units are supposed to have identical characteristics, these two curves will be symmetrical with respect to the origin. Also, plotted on Figure 3 is the sum of the curves for units 1 and 2. This curve then gives the total change in flux linkages in the secondary coils as a function of the alternating secondary current. It will be assumed the applied voltage is sinusoidal, and that the series voltage drop across the burden is negligible. It then can be shown that the necessary flux linkages in the secondary coils are sinusoidal.

$$e = \sqrt{2}E \sin \omega t; \quad \phi N = \frac{\sqrt{2}E10^8}{\omega} \cos \omega t$$

From Figure 3, the alternating current

Figure 2. Change of a-c coil flux linkages as a function of the alternating current

Figure 3. Required alternating current for sinusoidal applied alternating voltage and flux linkage

necessary for sinusoidal flux linkages developed in the units is shown. The alternating current that flows is essentially a series of positive and negative polarity rectangular pulses. The maximum value of the alternating current is nearly the direct current times the ratio of the d-c turns to a-c turns. If the slope of the saturation curve above the knee were zero, the alternating current would reverse instantly as it went through zero. As the slope is not zero, it takes the alternating current a definite length of time to reverse so the alternating current wave shape is trapezoidal rather than rectangular.

From Figure 3, the shape of the alternating voltage wave across each secondary can be determined. When the alternating current is positive, the core of unit Number 1 is almost completely saturated. There is very little flux change in unit Number 1, and consequently it develops very little voltage. Hence unit number 2 must develop most of the voltage when the alternating current is positive. As the flux change in number 2 is from zero to a maximum and back to zero, the voltage induced starts from a maximum to zero and to a minimum. During the half-cycle the alternating current is negative, the other unit will develop the induced voltage to oppose the applied alternating voltage.

The secondary alternating current is relatively insensitive to changes in alternating voltage. This is seen readily from Figure 3. If the alternating voltage and hence the a-c flux is decreased, it will take a little longer for the alternating current to reach its maximum value, but it will reach the same maximum value. The average alternating current will decrease some, but not nearly in proportion to the

voltage decreases. In a typical design, a 5 per cent change in voltage results in less than 1 per cent change in current. This is so slight that no precautions need be taken usually for voltage variations. The effect on the secondary current of changing the burden is about the same as that of changing the voltage. The secondary current does not decrease nearly as rapidly as the burden voltage drop increases.

The foregoing method is purely graphical. It is possible to make a mathematical analysis by assuming some certain formula for the saturation curve. In Appendix I a method is derived for simplifying the analysis using the actual saturation curve, and an approximate solution using a saturation curve of two straight lines. The latter approximation will give answers sufficiently close for practical purposes.

The analysis for the series case assumes a pure direct primary current. When the transductor is operating, alternating voltages appear across the d-c input coils. If the impedance of the d-c circuit is low, alternating currents will flow in the d-c circuit, and the foregoing analysis will not hold. Actually if the d-c impedance is very low, the analysis of the series connections is identical to that of the parallel connections. See reference 1. Ordinarily the d-c impedance will be very high.

Graphical Solution for Parallel Connections

Instinctively, one would not feel that the parallel connection, also shown in

Figure 4. Parallel connection of current transductor

Flux density in one core and total amperes on a-c turns basis as functions of time

Figure 5. Parallel connection, alternating current in each secondary, and alternating line current

Figure 1, could be used for current measurement. One would think that one or the other core would be always saturated, and the current flow would be unlimited. Such is not the case, however; the current is definitely limited, as will be shown now.

Each of the units of the parallel connection of Figure 1 operates independently, as each is connected directly, except for the meter drop, to the alternating voltage; and each has a definite primary direct current. The problem resolves itself into finding the alternating current flowing in one winding of a transformer when there is a pure direct current flowing in another.

Figure 4 shows the excitation curve for one of the cores. The current is on the secondary turns basis. Since there is a d-c magnetomotive force on the core, there must be a d-c component in the flux density, although its magnitude cannot be directly determined. As the applied voltage is sinusoidal, the flux density in the core also must vary sinusoidally, neglecting the resistance of the a-c winding.

If the value of the d-c flux in Figure 4 were zero, the total current required for sinusoidal flux variation would have no d-c component. If the d-c flux is not zero there will be a d-c component in the total current. It is fundamental that there can be no direct current flowing in a circuit consisting of a constant resistance and a constant or variable reactance supplied from an a-c supply after the transient currents have subsided. This is almost self-evident, but is demonstrated in Appendix II. It follows that the d-c component of the current in the total current, when there is a d-c component in the flux, can be supplied only from the d-c winding.

The d-c component of flux adjusts itself until the d-c component in the total current is equal to the direct current, all referred to a-c turns basis. The process of analysis is indirect: a value of d-c flux must be found by trial which gives the known value of direct current. In Figure 4, the d-c component of the current is shown as the dot-dash line, and as marked on the figure must be equal to $I_{dc}N_p/N_s$. If the dot-dash line is considered the zero line, the current as shown in Figure 4 will be the alternating current flowing in one secondary, for the alternating current would be instantaneously the total current minus $I_{dc}N_p/N_s$.

In Figure 5 is shown the alternating current in each secondary, and then the line current, which is the sum of the two. This process for determining the secondary currents is general. If some approximations are made, though, some very revealing facts can be deduced regarding the basic operation of this circuit. Referring to Figure 6, the initial part of the saturation curve is assumed vertical up to a value of flux density equal to or greater than B_{dc}. This will result in the total amperes being zero for a half-cycle or more. As was explained previously, the average value of the total current required must be $I_{dc}N_p/N_s$, shown again as the dot-dash line on Figure 6. Referring to the areas shown on Figure 6, it must be true

Figure 6. Parallel connection of current transductor

Flux density in one core and total amperes on a-c turns basis as functions of time. Same as Figure 4 except the initial part of the saturation curve is assumed vertical

Figure 7. Parallel connection, alternating current in each secondary, and a-c line current for idealized curve of Figure 6

$$A+B+C=I_{dc}\frac{N_p}{N_s}\frac{2\pi}{\omega}$$

$$A+C=D$$

Therefore

$$B+D=I_{dc}\frac{N_p}{N_s}\frac{2\pi}{\omega}$$

Again the alternating current flowing in each secondary is the current shown in Figure 6 with the dot-dash line as the zero line.

In Figure 7 is shown the current flowing in each secondary winding, and the line current, the sum of the two. It will be noted that the line current is exactly identical in shape to the total current in Figure 6. This is because the opposite secondary restores the d-c component of current lost in the secondary considered. It should be noted that this is only true if the total current in Figure 6 is zero for at least a half-cycle. It was shown above that the area under the total current wave was

$$B+D=I_{dc}\frac{N_p}{N_s}\frac{2\pi}{\omega}$$

which also is the area under the line a-c wave for a half-cycle. Therefore, the average value of the line alternating current for a half-cycle is

$$I_{ac\text{-}avg}=\frac{B+D}{\pi/\omega}=2I_{dc}N_p/N_s$$

It is evident then that the average value of the alternating line current is directly related to the direct current, regardless of the slope of the saturation curve above the knee. If the slope is small, the pulse of alternating current will be small in width and high in peak value. This will result in the line alternating current having a higher rms value, but the average value will still remain the same. If the slope above the knee is large, the pulse of the alternating current will be wider in width, and the rms value of the line current will be smaller.

A recent AIEE paper[1] gives a general method for determining the performance of the parallel-connected current transductor using the a-c saturation curve of the transductor. It should be noted that in the average curves in that paper the following relation exists where the b curves are vertical

$$b=\frac{I_0N_{dc}}{I_bN_{ac}}=0.5\frac{I_{avg}}{I_b};\ I_{avg}=\frac{2I_0N_{dc}}{N_{ac}}$$

This is true for the reasons outlined previously. Note that the definition of N_{ac} per the reference paper and N_s per this paper are not the same, but they are equal for the parallel connection. In Appendix II, a mathematical analysis is made with a saturation curve consisting of two straight lines that give an approximate analytical answer to the problem. The principle value of this solution is that the effect of the various constants on the performance of the transductor can be directly seen.

Formulas for a Two Straight-Line Saturation Curve

The secondary a-c saturation curve for one core is as shown in Figure 8, where the current should be sinusoidal and the voltage measured with an average reading voltmeter. Effective values of initial slope, X_i, and saturated slope, X_s are chosen, as well as a value for E_s, the saturation voltage. These should be chosen so as to take into consideration the rounded knee of the actual saturation curve.

For the series connection, the average value of the alternating current will be (see Appendix I)

$$I_{avg}=\frac{N_pI_{dc}}{N_s}\left[1-0.45\frac{X_sN_pI_{dc}}{EN_s}\right]-\frac{\sqrt{2}E_s}{X_i}+0.9\frac{E}{X_i}$$

The rms value of the current for the series connection is

$$I_{rms}=\frac{N_pI_{dc}}{N_s}\left[1-0.6\frac{X_sN_pI_{dc}}{EN_s}\right]^{1/2}-\frac{\sqrt{2}E_s}{X_i}+0.9\frac{E}{X_i}$$

The above formulas are for zero secondary resistance and series burden. To take these into account, subtract the resistance

Figure 8. Excitation curve for one core

The dotted curve is the actual curve, and the solid lines the approximate two straight-line curve

drop vectorially from the secondary excitation voltage to secure an effective value for E; and add one-half of the burden reactance to X_s and one-half to X_i to take the reactance into account. These formulas will apply down to approximately the point where the calculated current is in the order of magnitude of the alternating exciting current at zero direct current.

For the parallel connection, the average alternating line current is (Append'x II)

$$I_{ac1}=\frac{2N_pI_{dc}}{N_s}-\frac{2}{X_i}\left[\sqrt{2}E_s-2.32E+2.5X_s^{2/3}\left(\frac{N_pI_{dc}}{N_s}\right)^{2/3}E^{1/3}\right]$$

This expression is valid only if

$$I_{dc}\leq 0.583\frac{N_sE}{N_pX_s}$$

under which condition the alternating line current meets the requirement of having zero slope at current zero, see Figure 7. The burden voltage drop should be subtracted vectorially from the excitation voltage to secure the effective voltage to be used in the foregoing formula.

A very important characteristic of the current transductor is the change in the alternating current with a change in the alternating voltage. It is possible to compensate the transductor and calibrate the meters with the transductor so they will read correctly with a given excitation voltage and burden; but in the simple transductor, an error will still be introduced by a change in the excitation voltage. Approximately, for the series connection the per-unit change in average current is

$$\frac{\Delta I_{avg}}{I_{avg}}=\left(0.45\frac{N_pI_{dc}/N_s}{E/X_s}+0.9\frac{E/X_i}{N_pI_{dc}/N_s}\right)\frac{\Delta E}{E}$$

Figure 9 (left). 75,000-ampere d-c to 37.5-ampere a-c transductor. Series connected

The unit is shown on test with a special primary winding of 75 turns

Figure 11 (above). Oscillogram of tests made on 75,000-ampere current transductor at 50 per cent current

I_1 is the direct current, I_2 the alternating current. V_2 and V_3 are the voltages across the coils on each core

For most transductors, the latter part is negligible, and

$$\frac{\Delta I_{avg}}{I_{avg}} = 0.45 \frac{N_p I_{dc}/N_s}{E/X_s} \frac{\Delta E}{E}$$

For the rms current in the series connection

$$\frac{\Delta I_{rms}}{I_{rms}} = 0.3 \frac{N_p I_{dc}/N_s}{E/X_s} \frac{\Delta E}{E}$$

With the parallel connection, the per-unit change in the average line current is

$$\frac{\Delta I_{sol}}{I_{sol}} = \frac{E/X_f}{N_p I_{dc}/N_s}\left[2.32 - 0.83\left(\frac{N_p I_{dc}/N_s}{E/X_s}\right)^{2/3}\right]\frac{\Delta E}{E}$$

For most transductors, the quantity to the 2/3 power will be less than unity, and the expression becomes quite closely

$$\frac{\Delta I_{sol}}{I_{sol}} = 2.32 \frac{E/X_f}{N_p I_{dc}/N_s} \frac{\Delta E}{E}$$

In comparing the per-unit change in current in the series and the parallel cases, it should be kept in mind that the voltage E for the series connection will be about twice as much as for the parallel connection. Examples to be shown later indicate that the sensitivity to voltage change is about the same for the series or parallel connections.

Figure 10. Excitation curve for current transductor

75,000 amperes direct current to 37.5 amperes alternating current; 60-cycle excitation curve for each core. $X_f = 400$ ohms, $X_s = 2.4$ ohms, $E_s = 365$ volts

Noting the equations for the change in average current for the series connection, it is seen that the change varies as the direct current squared, whereas in the parallel connection it is independent of the direct current. Sometimes a capacitor is put across the a-c terminals of the transductor to neutralize the change in alternating current with a change in alternating voltage. It is evident that with the series connection, it can only be made to neutralize at one value of direct current, whereas with the parallel connection, it would be balanced for all direct currents. With the series connection, though a value of capacitance could be chosen that would be a compromise, and would help to some extent.

It also would be desirable to determine the effect of the burden on the alternating current. For the series connection, adding the reactance of the burden can be simulated by increasing both X_f and X_s by one-half the burden reactance, X_b. The change in the current due to a change in X_f is negligible. The effect of a change in X_s on the average current is

$$\Delta I_{avg} = -0.45\left(\frac{N_p I_{dc}}{N_s}\right)^2 \frac{\Delta X_s}{E}$$

and approximately

$$\frac{\Delta I_{avg}}{I_{avg}} = -0.225 \frac{I_{avg}\,\Delta X_b}{E}$$

For example, if the burden per cent reactance drop were 10 per cent based on the secondary excitation voltage, the secondary current would decrease 2.25 per cent. To determine the change in alternating current for the series connection due to the burden and secondary resistance, use is made of the relation developed in Appendix I; the secondary resistance drop is subtracted vectorially from the applied voltage to secure the effective voltage applied to the transductor.

$$E_r = [E^2 - I_{avg}^2 R_b^2]^{1/2} \cong E - \frac{(I_{avg}R)^2}{2E}$$

The change in the voltage applied to the transductor from the voltage with zero resistance is

$$\frac{\Delta E_r}{E} = \frac{E_r - E}{E} = -\frac{1}{2}\left(\frac{I_{avg}\,\Delta R}{E}\right)^2$$

If the resistance drop is, for example, 20 per cent, the reduction in the voltage is 2 per cent. The reduction in the alternating current will be still less, as would be determined by the formulas for the change in current with a change in voltage. The net effect is that the alternating current changes but little for the addition of resistance, but there is a

Table I. Test and Calculated Values of Alternating Current for a Current Transductor, Series Connection

Primary current 75,000 amperes direct current; rated secondary current = 37.5 amperes alternating current; secondary excitation voltage 440 volts, 60 cycles; series connected, $N_p = 1$ turn; $N_s = 2{,}000$ turns; $E_s = 365$ volts; $X_f = 400$ ohms; $X_s = 2.4$ ohms; secondary resistance = 0.88 ohm; rated secondary burden: 0.75 ohm

Primary Amperes, D-C	Excitation Volts	Burden Resistance, Ohms	Average Current, Amperes Test	Average Current, Amperes Calc.	Rms Current Amperes Test	Rms Current Amperes Calc.
100,000	440	0.375			44.7	45.4
75,000	440	0			34.6	34.8
75,000	480	0.375			34.9	35.0
75,000	440	0.375	33.4	33.7	34.7	34.8

18,750	440	0.375	8.5	8.9	8.7	8.9
7,500	440	0.375	3.5	3.4	4.0	3.4

fair amount of change due to addition of reactance.

For the parallel connection, as was pointed out previously, the effect of the series resistance and reactance is to reduce the effective voltage applied to the transductor. The formula for the change in voltage due to the resistance derived above applies. For the addition of reactance

$$E_r = [E^2 - I^2R_b^2]^{1/2} - IX_b$$

$$\frac{\Delta E_r}{E} = -\frac{I\,\Delta X_b}{E}$$

For the parallel connection then, the same percentage increase in reactance drop and percentage decrease in applied voltage will result in the same change in the alternating current.

Construction of Some Current Transductors, and Comparison of Experimental and Calculated Results

As the current transductor has two sets of secondary coils and cores, the device is constructed very similarly to double-secondary current transformers. Figure 9 shows a 75,000-to-37.5 ampere current transductor that will be used for measuring current in an aluminum reduction line. Each core on the unit has 14 coils. The primary bus opening is 11 by 34 inches. It was necessary to build a primary winding of 75 turns around the unit for purposes of testing as current in the order of 75,000 amperes was not readily available. This unit is series connected, with lightning arresters connected across the coils on each core. With the series connection, if the primary current should change suddenly, while the primary current is small, a transient voltage is built up across each set of coils on the two cores. In the higher current ratings, it is difficult to provide enough insulation in the coils to stand this voltage, so lightning arresters are used. The secondary coils may seem to be spaced unnecessarily far from the primary bar, but the longer the length of the core, the thinner the coils will be. This will result in a smaller air-cored reactance, and hence saturated reactance X_s, and consequently better performance.

In Table I are given the data and test results for the 75,000-ampere current transductor. The excitation curve for both cores on this unit is shown in Figure 10. From this curve, values of X_t, X_s, and E_s can be determined.

In Table I are listed the test and calculated values of average and rms alternating current. The average current was read by a rectifier voltmeter reading the voltage across a known resistance. The rms current was read by a dynamometer ammeter. Sample calculations for this transductor follow for 75,000-ampere 440-volt excitation 0.375-ohm burden point

$$I_{avg} = \frac{N_pI_{dc}}{N_s}\left[1 - 0.45\frac{X_t}{E}\frac{N_pI_{dc}}{N_s}\right] - \frac{\sqrt{2}E_s}{X_t} + 0.9\frac{E}{X_t}$$

$$= \frac{(1)(75{,}000)}{2{,}000}\left[1 - \frac{(0.45)(2.4)(37.5)}{440}\right] - \frac{\sqrt{2}(365)}{400} + 0.9\frac{440}{400}$$

$$= 37.5[1 - 0.092] - 1.29 + 0.99 = 33.7$$

To take into account the secondary resistance which is 0.375 + 0.88 = 1.255 ohms

$$\frac{\Delta E_r}{E} = -\frac{1}{2}\left(\frac{I\,\Delta R}{E}\right)^2 = -\frac{1}{2}\left(\frac{33.7 \times 1.255}{440}\right)^2 = -0.0047$$

$$\frac{\Delta I_{avg}}{I_{avg}} = 0.45\frac{N_pI_{dc}/N_s}{E/X_s}\frac{\Delta E}{E} = \frac{(0.45)(37.5)}{440/2.4}(-0.0047) = -0.00043$$

The change due to the addition of the burden is negligible. From the test data it can be seen that addition of the burden causes hardly any change in the current. This value of 33.7 amperes calculated is 1 per cent higher than the test value of 33.4 amperes.

For the rms current, at 75,000-amperes, 440-volts' excitation, and 0.375 ohms' burden, the current calculates 34.8 amperes. A separate calculation can be made for the 480-volt point, or the change calculated as follows

$$\frac{\Delta I_{rms}}{I_{rms}} = 0.3\frac{N_pI_{dc}/N_s}{E/X_s}\frac{\Delta E}{E} = \frac{(0.3)(37.5)}{440/2.4}\frac{(480-440)}{440} = (0.062)(0.091) = 0.0057$$

The secondary current at 480 volts would be

$$(1.0057)(34.8) = 35$$

The measured values were 34.7 and 34.9 amperes respectively.

Figure 11 is an oscillogram of a test made on the 75,000-ampere transductor. This oscillogram shows the alternating voltage on each of the a-c coils, the direct current, and the alternating current. The test was made at about 50 per cent direct current. The oscillogram shows the transient response of the transductor with a suddenly applied direct voltage. The direct current rises to its steady-state value. The alternating current has the characteristic square wave shape of the series-connected transductor. It follows the direct current very closely; the transient response of the series-connected current transductor is very excellent. The top two curves show the alternating voltage on the two a-c coils. Before application of the direct current, the voltages on the coils are sinusoidal and are about equal. As soon as the direct current is applied, each core is saturated in turn for a half-cycle. The voltage must appear across the other coil. Hence the alternating voltage on each a-c coil is double its normal value for a half-cycle and zero the other half-cycle after the direct current is applied.

The ripple in the direct current was due to the alternating voltage appearing across the d-c coils. This is a double-frequency voltage. Ordinarily, the impedance of the d-c circuit is large enough to keep the direct current uniform; but in this case, there was not quite enough impedance to make the direct current smooth

Figure 12 is a 2,000-to-1 ampere current transductor of the through-type construction. A unit of similar construction rated 4,000-to-4 amperes was tested on the parallel connection. The data and results for this unit are shown in Table II. The excitation curve for each core is shown in Figure 13. Two sets of calculated figures are shown in Table II. One set is calculated according to the two straight-line saturation curve method outlined previously and the other set is calculated by the method

Table II. Test and Calculated Values of Alternating Current for a Current Transductor, Parallel Connection

Primary current 4,000 amperes direct current; rated secondary current: 4 amperes alternating current; secondary excitation voltage: 58 volts, 60 cycles; parallel connected, $N_p = 1$; $N_s = 1{,}930$ turns; $E_s = 110$ volts; $X_t = 1{,}100$ ohms; $X_s = 11.7$ ohms; secondary resistance: 1.35 ohms; rated secondary burden: 2.5 ohms

Primary Amperes, D-C	Excitation Volts	Burden Resistance, Ohms	Test	Average Current, Amperes Calculated 2 Straight-Line	Universal Curve
4,000	72	0.8	4.20	4.00	4.11
4,000	58	0.8	4.14	3.90	4.07
4,000	43	0.8	4.02	3.91	
3,000	58	0.8	3.14	2.96	3.05
2,000	72	0.8	2.15	1.99	2.05
2,000	58	0.8	2.08	1.95	2.03
2,000	43	0.8	2.01	1.89	1.97
1,000	58	0.8	1.10	0.95	1.00
400	58	0.8	0.45	0.35	0.40

Figure 12. A 2,000-to-1 ampere current transductor

outlined in reference 1. The latter figures are closer to the test results, about 2 per cent low, while the two straight-line approximation calculates about 6 per cent low. The excitation-curve data was taken with an iron vane voltmeter; if a rectifier-type voltmeter had been used, the curve would be closer to the d-c magnetization curve.

Series Versus Parallel Connection

The series connection of the a-c coils is the simpler circuit, but there may be cases in which the use of the parallel connection is more desirable. If the d-c circuit has very low impedance, appreciable alternating current may circulate if the series connection is used. This will throw off the calibration of the instrument, although the variation is not a major one. With the parallel connection there is practically no alternating voltage across the d-c coil, and a parallel-connected transductor would be unaffected by the impedance of the d-c circuit. In other circuits, it is possible that the circuit could not tolerate the alternating voltage developed across the d-c coil. With these, the parallel connection may be more desirable.

When the direct current is small, with the series connection, there are times during a cycle when neither core is saturated. If the direct current should change rapidly at these low values of direct current, high peak voltages may be induced across the a-c coils. This does not occur at higher values of direct current, as under this condition one of the cores is always saturated, and the peak voltage induced in the other coil is short-circuited through the saturated coil and the a-c supply. In the lower current ratings, it may be possible to design the coil to stand the voltage. In higher current ratings, and where the peaks do not occur too often, it is possible to protect the coils with lightning arresters. Where too much current passes through the lightning arrester, a limit may be reached where this method is not practical. The parallel connection can be used in these cases. With this connection, the a-c component circulates harmlessly around the a-c coils. Another solution would be to wind the a-c coils for a lower voltage, which would then directly decrease the number of a-c turns and the peaked voltages.

Another application that might dictate the use of the series-connected current transductor is one where it is desired that the transient response will be very rapid. With the series connection, a ripple frequency in the direct current up to six times the excitation frequency should be faithfully reproduced in the alternating current. When the direct current is suddenly applied, the alternating current will follow the direct current faithfully as is shown in Figure 11. With the parallel connection, a sudden change in the direct current causes an equal and opposite current to circulate between the a-c coils. Until this current decays, there is no increase in the effective d-c magnetomotive force on the cores. It will require one or two cycles on a 60-cycle basis for the circulating current through the a-c coils to decay. For use with indicating instruments, this is sufficiently rapid, but for relaying, it may not be.

Accuracy

If the ammeters are specially calibrated with the current transductors, the only errors that can arise in application are those due to changes in excitation voltage and burden impedance. The latter about amounts to the former, for either one has the effect of changing the excitation voltage at the terminals of the transductor. By designing for higher values of excitation voltamperes, the sensitivity of the series-connected transductor to voltage changes can be reduced from that of the standard design. To demonstrate this, if it is assumed that the following sequence takes place:

Turns remain constant.
Core area increases.
$E_a \propto$ core area.
$E \propto$ core area.
$X_t \propto$ core area.
Excitation $VA \propto$ core area.

Then E_a/X_t and $E/_tX$ remain constant. Although casually it would be assumed that X_s also is proportional to the core area, such is not the case, for in the usual design X_s includes much flux in the air. Increasing the core area will not result in

Figure 13. Excitation curve for current transductor

4,000 amperes direct current to 4 amperes alternating current; 60-cycle excitation curve for each core. $X_t = 1{,}100$ ohms, $X_s = 11.7$ ohms, and $E_a = 110$ volts

a proportionate increase in X_s. Consequently, the ratio of X_s/E will decrease as the core area increases. Referring to the equations for average and rms current for the series connections, it will be seen that this will result in decreased sensitivity to voltage changes. Another approach is possible where the alternating exciting current for the transductor at zero primary direct current is smaller than is necessary. In the lower current designs of around 2,000 amperes, this is not true, but around 10,000 to 20,000 amperes the current does become less than 1 per cent of rated current. If the mean length of the core is increased, X_t will decrease. X_s will decrease, as the thickness of the coil is decreased and the length increases. Increasing the length of the core is quite effective in reducing voltage sensitivity where the exciting current is not a limit. At the present time, a change of 2 per cent in current for a 10 per cent change in excitation voltage results in a unit that has reasonable dimensions and excitation-voltampere requirements. For this limit, 2,000 amperes direct current requires about 110 voltamperes excitation. The excitation increases more rapidly than the direct current so that at 20,000 amperes direct current, about 2,600 voltamperes are required.

With the parallel-connected transductor, apparently the major cause of sensitivity to voltage variations is due to X_t, the initial reactance, as long as the saturated reactance is less than a certain

value. Increasing the core area will increase X_t, and if the excitation voltage is left unchanged, sensitivity to voltage change will decrease. The limit occurs when X_t increases to the point where the alternating line current does not have zero slope at current zero. It would appear with the parallel-connected current transductor that a high permeability material would have definite advantages. Also, as was pointed out previously, a capacitor may be put on the terminals of the transductor to correct for voltage sensitivity. The use of a capacitor for such an application is questionable, as one could never be certain without testing the capacitor whether it is functioning properly.

Essentially, duplicate current transductors are interchangeable. How closely this is met can be demonstrated as follows. For the series-connected current transductor, the average current is

$$I_{avg} = \frac{N_p I_{do}}{N_s}\left[1 - 0.45\frac{X_t N_p I_{do}}{E\ N_s} - \frac{\sqrt{2}E_s/X_t}{N_p I_{do}/N_s} + \frac{0.9E/X_t}{N_p I_{do}/N_s}\right]$$

It is possible to adjust the iron stack on test so that the unit will have correct ratio at some particular value of current; for instance, 100 per cent current. At some other value of current, the ratio may not be the same as the reference unit though. For example, if the values in the foregoing equation at 100 per cent direct current are

$$I_{avg} = 1.118[1 - 0.10 - 0.02 + 0.015] = 1$$

At 50 per cent direct current, the value of I_{avg} will be

$$I_{avg} = 0.559[1 - 0.05 - 0.04 + 0.03] = 0.525$$

The dial of the meters would be calibrated to these values of currents, and would read properly. If another unit though, has other values of X_t, X_s, and E_s, the core stack would be adjusted so I_{avg} would be one at 100 per cent direct current. For instance, if another unit had these values at 100 per cent direct current.

$$I_{avg} = 1.118[1 - 0.095 - 0.04 + 0.03] = 1$$

But at 50 per cent direct current, I_{avg} now will be

$$I_{avg} = 0.559[1 - 0.0475 - 0.08 + 0.06] = 0.521$$

This is an error of 3/4 per cent based on the actual current, or 3/8 per cent based on rated current. These represent about the values for an average unit, and the variation that might be expected between units.

For the series-connected current transductor, the position of the return conductor may have some effect on the accuracy. Ideally, the a-c ampere turns should be distributed around each core so that for each element of length of the core, the a-c ampere turn can balance the d-c ampere turns. If this is not the case, there is danger of local saturation due to the return conductor principally. If the core is of sufficiently large size, the flux density in the core due to leakage flux caused by the return conductor may be small enough so that it will not produce local saturation of the core. The cores in current transductors are relatively small in area, so the ratio between the surface area and the cross-sectional area is large. These relative proportions tend to increase the leakage flux density in the core. Local saturation of the core due to the return conductor is almost always a problem in current transductors. It is best solved by winding the coils on each core so they can be connected in parallel. The alternating currents will then automatically divide between the various paths so that for the length of each coil the d-c and a-c ampere turns will be balanced. The number of parallel paths to use can best be determined by experience. Tests were made on a 2,000-ampere transductor at rated current with the following results. With two parallel circuits on each core, the secondary current was 100 per cent with the return conductor distant, and was 98.5 per cent with the return conductor close to the transductor. With all turns in series on each core and with the return conductor close to the transductor, the secondary current was 87 per cent. It is somewhat surprising that the secondary current decreases when the return conductor is brought closer to the transductor; instinctively, one would feel it should increase.

Conclusions

The current transductor, a device with many of the characteristics of the a-c transformer, is a practical piece of apparatus for metering direct currents. It has a secondary a-c output that is proportional to the input direct current and that is little affected by the burden in the metering circuit or the voltage or frequency of the excitation voltage. The secondary metering circuit is electrically isolated from the d-c circuit that is being metered.

The time of response is very rapid with the series-connected current transductor in the order of a fraction of a cycle. With the parallel-connected transductor, the time is in the order of one to two cycles, which is still sufficiently rapid for use with indicating instruments.

With meters specially calibrated with the transductors, and with voltage variations limited to 2 or 3 per cent, a maximum error in the order of 1/2 of 1 per cent plus the meter tolerance (about 1/2 of 1 per cent for the best meters) should be practical. For interchangeable manufacture of transductors and meters, and voltage variations of about 5 per cent, over-all accuracy of 2 per cent can be attained. It is possible to have better accuracy with larger excitation voltamperes, to a limit dependent on the characteristics of the core material.

The transductor will do some things the d-c shunt will not do. Some devices, such as thermal relays, would not operate too satisfactorily from a d-c shunt. The transductor provides insulation between the d-c circuit and the metering circuit. Transductors have been built for currents of 75,000 amperes and tested at 100,000 amperes direct current. This unit had 16.5-kva excitation at 75,000 amperes. The excitation can be reduced at the expense of accuracy. Transductors for higher currents than these should be feasible without any major difficulties. By proper design, the effect of the position of the return conductor can be made negligible, even at these high currents.

The transductor is not responsive to the direction of the direct current. The magnitude and phase position of the alternating current are unchanged with reversal of the direct current. There are various ways to overcome this difficulty by various auxiliary circuits or devices; but the inherent polarity indication of the d-c meter would be an advantage that would make it difficult to justify a transductor for these installations. Nevertheless, the transductor is a new device that will permit a new approach to an old problem. It should find a permanent place for itself in the field of instrumentation.

Appendix I. The Series-Connected Current Transductor

The centimeter-gram-second system of units is used in these appendixes. Based on the graphical method shown in Figure 3, it is possible, using the saturation curve and some approximations, to deduce some relations that will make the process of calculating performance somewhat simpler. Referring to Figure 14, top, the saturation curve for the core material is shown. This is really the effective curve as built into the unit. In the bottom part of the figure is shown the effective saturation curve from the secondary a-c terminals, which is the

Figure 14 (left). Curves for series connection, for mathematical analysis

Figure 15 (right). Approximate curve for determining the rms current for series connection

sum of the ΔB curves for each of the cores for some value of d-c magnetomotive force, H_0. Also shown are the required flux density curve for sinusoidal applied secondary voltage and the resultant H curve as functions of time. A number of quantities are shown on the lower curve. H_0 is the magnetomotive force due to the primary direct current. B_0 is the sum of the flux changes in the two cores if an a-c magnetomotive force equal to H_0 is applied. The curve for ΔB is assumed to be a straight line above B_t, until the top knee is reached. It is evident by comparing the top and bottom curves that the values of B_0, B_t, and H_t can be read directly from the top excitation curve as shown.

The transductor is designed so that in virtually all cases the maximum total a-c flux density will be well in excess of B_t, so that referring to Figure 14, the relation between the a-c flux density and time will be virtually a straight line-up to a value of flux density change equal to B_t. Also, as we have pointed out, H is a linear function of ΔB above B_t.

To determine the average value of the a-c magnetomotive force, the areas 1 and 3 in Figure 14 must be determined. But the area 1 is equal to the area 2 times the ratio, ψ/B_t. This is true as long as the flux changes linearly with time to the angle ψ. The sum of the two areas indicated as 2 in the top excitation curve can be shown equal to the area 2 in the bottom curve. Then

$$B_m=\frac{\sqrt{2}E10^8}{\omega N_s A}\text{ gauss}$$

$$\psi=B_t/B_m=\frac{B_t\omega N_s A}{\sqrt{2}E10^8}\text{ radians}$$

$$\frac{\psi}{B_t}=\frac{1}{B_m}=\frac{\omega N_s A}{\sqrt{2}E10^8}$$

The relation between ΔB and H for ΔB larger than B_t is

$$\Delta B-B_0=\frac{B_0-B_t}{H_t}(H-H_0)$$

but

$$\Delta B=B_m\sin\theta$$

$$H=H_0+\frac{H_t}{B_0-B_t}(B_m\sin\theta-B_0)$$

$$H=H_0-\frac{H_tB_0}{B_0-B_t}+\frac{H_tB_m}{(B_0-B_t)}\sin\theta$$

The area 3 is

$$\text{Area 3}=\int_\psi^{\pi/2}H\,d\theta$$

$$=\left[H_0-\frac{H_tB_0}{B_0-B_t}\right]\left(\frac{\pi}{2}-\psi\right)+\frac{H_tB_m}{(B_0-B_t)}\cos\psi$$

The average a-c magnetomotive force then is

$$H_{ac\ avg}=\frac{(\text{area 1})+(\text{area 3})}{\pi/2}\text{ oerstads}$$

$$=\left\{(\text{area 2})(1/B_m)+\left[H_0-\frac{H_tB_0}{B_0-B_t}\right]\times\left(\frac{\pi}{2}-\psi\right)+\frac{H_tB_m}{(B_0-B_t)}\cos\psi\right\}\frac{2}{\pi}$$

where

$$\psi=B_t/B_m=\frac{B_t\omega N_s A}{\sqrt{2}E10^8}$$

The determination of the rms value of the a-c magnetomotive force can be approximated by the following method. Although the portion of the curve corresponding to area 1 is curved, it could be approximately replaced by a polygon as shown in Figure 15, which has the same area as area 1.

$$(\text{area 1})=(\text{area 2})\frac{1}{B_m}=\left(\psi-\frac{\epsilon}{2}\right)(H_0-H_t)$$

$$\epsilon=2\left[\psi-\frac{(\text{area 2})}{B_m(H_0-H_t)}\right]$$

Then

$\int_0^{\pi/2}H^2d\theta$ is

$$\int_0^\epsilon\left[\frac{H_0-H_t}{\epsilon}\theta\right]^2d\theta+\int_\epsilon^\psi(H_0-H_t)^2d\theta+\int_\psi^{\pi/2}\left[H_0-\frac{H_tB_0}{B_0-B_t}+\frac{H_tB_m}{B_0-B_t}\sin\theta\right]^2d\theta$$

$$=(H_0-H_t)\left(\psi-\frac{2\epsilon}{3}\right)+\left[H_0-\frac{H_tB_0}{B_0-B_t}\right]^2\times\left(\frac{\pi}{2}-\psi\right)+2\left(H_0-\frac{H_tB_0}{B_0-B_t}\right)\frac{H_tB_m}{B_0-B_t}\times\cos\psi+\left(\frac{H_tB_m}{B_0-B_t}\right)^2\frac{\pi}{4}$$

The rms value of H_{ac} then will be

$$H_{ac\text{-}rms}=\left[\frac{2}{\pi}\int_0^{\pi/2}H^2d\theta\right]^{1/2}\text{ oerstads}$$

Approximation Using Two Straight-Line A-C Excitation Curve

In general, it is more convenient to take the a-c saturation curve instead of the d-c saturation curve. The assumption will be made that the excitation current and voltage are sinusoidal and the permeability as determined from the peak flux and peak current is the same as the d-c permeability. If the exciting current is maintained sinusoidal and the voltage read with an average voltmeter, the peak current-peak flux curve should approximate quite closely the d-c excitation curve. Figure 8 shows an idealized excitation curve with an initial slope X_t and a final slope X_s. Saturation voltage is E_s. This curve is for one core.

$$B_m=\frac{\sqrt{2}E10^8}{\omega N_s A};\quad H=\frac{\sqrt{2}\,0.4\pi N_s I}{l}$$

The following values then apply

$$H_t=\frac{\sqrt{2}\,0.4\pi N_s E_s}{l\,X_t}$$

$$H_0=\frac{0.4\pi N_p I_{do}}{l}$$

$$B_t=\frac{\sqrt{2}\left[X_s2\left(\frac{I_{do}N_p}{\sqrt{2}N_s}-\frac{E_s}{X_t}\right)\right]10^8}{\omega N_s A}$$

$$B_0=\frac{\sqrt{2}\left[E_s+\frac{2X_sI_{do}N_p}{\sqrt{2}N_s}-\frac{X_sE_s}{X_t}\right]10^8}{\omega N_s A}$$

$$\text{Area 2}=\frac{1}{2}B_t(H_0-H_t)$$

$$=\frac{2X_s0.4\pi10^8}{\omega Al}\left(\frac{I_{do}N_p}{\sqrt{2}N_s}-\frac{E_s}{X_t}\right)^2$$

$$\psi=B_t/B_m=\frac{2X_s\left(\frac{I_{do}N_p}{\sqrt{2}N_s}-\frac{E_s}{X_t}\right)}{E}$$

Substituting these expressions in those for the average magnetomotive force above, and solving for the average line current, I_{avg}

$$I_{avg}=\frac{2}{\pi}\left\{\frac{X_s}{\sqrt{2}E}\left(\frac{I_{do}N_p}{N_s}-\sqrt{2}\frac{E_s}{X_t}\right)^2+\left[\frac{N_pI_{do}}{N_s}-\frac{\sqrt{2}E_s}{X_t}\right]\times\left(\frac{X_t-X_s+\frac{\sqrt{2}X_tX_sI_{do}N_p}{N_sE_s}}{X_t+X_s}\right)\times\left(\frac{\pi}{2}-\psi\right)+\frac{\sqrt{2}E}{X_t+X_s}\cos\psi\right\}$$

In this form the equation is rather difficult to use. A very useful and quite accurate approximation can be secured if X_t is large, as is usually the case, by letting $y=1/X_t$ in the expression for I_{avg}. Then expand I_{avg} as a function of y in a Maclaurin's series

$$I_{avg}=(I_{avg})_{y=0}+\left(\frac{dI_{avg}}{dy}\right)_{y=0}y$$

If this is done and X_t substituted back in, the resulting expression is

$$I_{avg}=\frac{N_pI_{dc}}{N_s}\left[1-\frac{\sqrt{2}}{\pi}\frac{X_s}{E}\frac{N_pI_{dc}}{N_s}\right]-\left[1-\frac{2\sqrt{2}X_sI_{dc}N_p}{\pi EN_s}\right]\left[1+\frac{\sqrt{2}X_sI_{dc}N_p}{N_sE_s}\right]\times\frac{\sqrt{2}E_s}{X_t}+\left(\cos\frac{\sqrt{2}X_sI_{dc}N_p}{EN_s}\right)\frac{\sqrt{2}\,2E}{\pi X_t}$$

In most cases

$$\frac{X_sI_{dc}N_p}{EN_s}\text{ and }\frac{X_sI_{dc}N_p}{E_sN_s}<{}^1/_4$$

and even if they are somewhat larger, the coefficients of $\sqrt{2}E_s/X_t$ and $2\sqrt{2}E/\pi Xi$ are such the coefficients will still be nearly unity. The expression reduces to

$$I_{avg}=\frac{N_pI_{dc}}{N_s}\left[1-\frac{\sqrt{2}}{\pi}\frac{X_s}{E}\frac{N_pI_{dc}}{N_s}\right]-\frac{\sqrt{2}E_s}{X_t}+\frac{2\sqrt{2}E}{\pi X_t}$$

A very similar process may be followed to find the value of the rms current. The expression for the rms current is

$$I_{rms}=\sqrt{\frac{2}{\pi}}\times\left\{\left(\frac{I_{dc}N_p}{N_s}-\frac{\sqrt{2}E_s}{X_t}\right)^2\frac{\psi}{3}+\left[\frac{I_{dc}N_p}{N_s}-\frac{\sqrt{2}\left(E_s+\frac{\sqrt{2}X_sI_{dc}N_p}{N_s}-\frac{X_s}{X_t}E_s\right)}{X_t+X_s}\right]^2\times\left(\frac{\pi}{2}-\psi\right)+2\left[\frac{I_{dc}N_p}{N_s}-\frac{\sqrt{2}\left(E_s+\frac{\sqrt{2}X_sI_{dc}N_p}{N_s}-\frac{X_s}{X_t}E_s\right)}{X_t+X_s}\right]\times\frac{\sqrt{2}E}{X_s+X_t}\cos\psi+\left(\frac{\sqrt{2}E}{X_s+X_t}\right)^2\frac{\pi}{4}\right\}^{1/2}$$

Expanding the part inside the brackets in a Maclaurin's series in y, where $y=1/Xi$, and then resubstituting in the expression $y=1/X_t$

$$I_{rms}=\sqrt{\frac{2}{\pi}}\times\left\{\left(\frac{I_{dc}N_p}{N_s}\right)^2\left(\frac{\pi}{2}-\frac{2\sqrt{2}X_sI_{dc}N_p}{3E\ N_s}\right)+\frac{1}{X_t}\left[\frac{2\sqrt{2}I_{dc}N_pE}{N_s}\times\cos\frac{\sqrt{2}X_sI_{dc}N_p}{E\ N_s}-2\sqrt{2}\frac{I_{dc}N_p}{N_s}\times\left(\frac{\pi}{2}-\frac{\sqrt{2}X_sI_{dc}N_p}{N_s\ E}\right)\left(E_s+\frac{\sqrt{2}X_sI_{dc}N_p}{N_s}\right)\right]\right\}^{1/2}$$

Neglecting the smaller parts of this expression

$$I_{rms}=\left\{\left(\frac{I_{dc}N_p}{N_s}\right)^2\left(1-\frac{4\sqrt{2}X_sI_{dc}N_p}{3\pi EN_s}\right)+\frac{1}{X_t}\left[\frac{4\sqrt{2}I_{dc}N_pE}{\pi N_s}-\frac{2\sqrt{2}I_{dc}N_pE_s}{N_s}\right]\right\}^{1/2}$$

Figure 16. Phase angle at which alternating current is zero, with addition of resistance in series connection

which is very closely

$$I_{rms}=\frac{I_{dc}N_p}{N_s}\sqrt{1-\frac{4\sqrt{2}X_sI_{dc}N_p}{3\pi E\ N_s}}+\frac{2}{\pi}\frac{\sqrt{2}E}{X_t}-\frac{\sqrt{2}E_s}{X_t}$$

Addition of Series Burden in A-C Circuit

The addition of series reactance can be taken care of by adding to the values of X_s and X_t, a value equal to one-half of the series reactance. If this is done, it is seen from the foregoing analysis that at all points on a cycle the reactance is increased by twice one-half of the series reactance, which is what is desired. This makes it possible to use the same formula developed previously.

The addition of series resistance is more complicated. If there is no resistance in series with the a-c circuit, the phase angle at which the current goes through zero must lag the voltage zero by 90 degrees. Addition of resistance will reduce this phase angle. As a first approximation it will be assumed the current reverses instantaneously at current zero.

Then, referring to Figure 16, the following must be true

$$\int_0^{2\pi}ie\,d\theta=\frac{\sqrt{2}EI_{dc}N_p}{N_s}\left[\int_0^{\gamma}-\sin\theta\,d\theta+\int_{\gamma}^{\gamma+\pi}\sin\theta\,d\theta\int_{\gamma+\pi}^{2\pi}\sin\theta\,d\theta\right]=\frac{\sqrt{2}EI_{dc}N_p}{N_s}4\cos\gamma=\left(\frac{I_{dc}N_p}{N_s}\right)^2R2\pi$$

$$\cos\gamma=\frac{\pi}{2}\frac{I_{dc}N_p}{N_s}\frac{R}{\sqrt{2}E}$$

where R is the series resistance in ohms and includes the secondary resistance of the current transductor. This equality comes from the fact there can be no net energy storage in the inductance over a full cycle. The voltage induced in the transductor is

$$\sqrt{2}E\sin\omega t-iR$$

Again as a first approximation it is assumed the current reverses instantaneously at current zero.

The flux change in the core to develop this voltage is

$$\Delta\phi=\frac{10^8}{N_s}\int[\sqrt{2}E\sin\omega t-iR]dt=-\frac{\sqrt{2}\,E10^8}{\omega N_s}\cos\omega t-\frac{10^8}{N_s}\int iRdt+C$$

Also on Figure 16 are shown $\Delta\phi_1$, and $\Delta\phi_2$ which are the first and second parts of this equation. C is chosen so that $\Delta\phi_2$ has no d-c component.

Referring to Figure 14, if X_t is very large, it is apparent from the ΔB versus H curve that after the first knee at B_t the secondary current is constant and proportional to H_0, regardless of how the flux varies if the flux is larger than B_t. This will assume X_t is infinite, and that the change in current when X_t is not infinite is the same, whether R is zero or not, as long as the series drop through R is small compared to the applied voltage. The time required for the current to reverse is the same as the time for ΔB to change from $-B_t$ to $+B_t$. Referring to Figure 16, the current has been assumed rectangular, although it really is not. It is most likely the current is not even a straight line as it goes through zero, but it would not be too bad an approximation to say that the $\Delta\phi_2$ curve, which is essentially the integral of the "i" curve, is constant over the interval of the transient reversal of i. The time rate of change of $\Delta\phi$ is then the same as that of $\Delta\phi_1$. The time required for the current to reverse is then inversely proportional to the value of the time rate of change of $\Delta\phi_1$ at the angle γ. It is possible, though, to have a similar circuit with zero resistance and with a smaller alternating voltage that will cause the same rate of change of flux at current zero. This circuit should give the same current wave shape as our desired circuit, as the time required for the flux to reverse from $-B_t$ to $+B_t$ is the same. Call this effective voltage E_r

$$\Delta\phi_R=-\frac{\sqrt{2}E_r10^8}{\omega N_s}\cos\theta$$

$$\left(\frac{d\,\Delta\phi_r}{d\theta}\right)_{\theta=\pi/2}=+\frac{\sqrt{2}E_r10^8}{\omega N_s}$$

And for the actual voltage E

$$\Delta\phi=+\frac{\sqrt{2}E10^8}{\omega Ns}\cos\theta$$

$$\left(\frac{d\,\Delta\phi}{d\theta}\right)_{\theta=\gamma}=+\frac{\sqrt{2}E10^8}{\omega N_s}\sin\gamma=+\frac{\sqrt{2}E10^8}{\omega N_s}\sqrt{1-\left[\frac{\pi}{2}\frac{I_{dc}N_p}{N_s}\frac{R}{\sqrt{2}E}\right]^2}$$

Equating the two

$$E_r=\sqrt{E^2-\left[\frac{\pi}{2}\frac{I_{dc}N_p}{N_s}\frac{R}{\sqrt{2}}\right]^2}$$

The quantity $\pi/2\sqrt{2}=1.11$; so very closely, the effective voltage applied to the reactor is the *vector* difference between applied voltage and secondary resistance drop.

Appendix II. Solution for the Parallel Connection

In a series circuit consisting of constant resistance and constant or variable react-

ance which is supplied from an a-c supply, there cannot be any d-c component of current in the steady state.

$$E \sin(\omega t+\theta) = iR + \frac{d(N\phi)}{dt}10^{-8}$$

$$\int_0^\infty E \sin(\omega t+\theta)dt = \int_0^\infty \left[iR + \frac{d(N\phi)}{dt}10^{-8}\right]dt$$

$$\int_0^\infty E \sin(\omega t+\theta)dt = \int_0^\infty iRdt + 10^{-8}\left[N\phi\right]_0^\infty$$

As there is a definite resistance in the circuit, the current cannot be infinite. Also with all magnetic materials, the permeability is finite; therefore the flux linkages, the last term in the equation above, must be finite. The term to the left of the equal sign also is finite. Hence the term involving the current to the right of the equal sign must be finite, and therefore the d-c component of this current must approach zero as time approaches infinity. A variable reactance cannot produce rectification, a variable resistance can. With the series-connected current transductor, the alternating current that was determined had no d-c component, so the above principle did not need to be considered. With the parallel-connected current transductor, use was made of this principle.

A previous paper[1] gives a general method for calculating performance of the parallel-connected current transductor. The method is very good and has the desired accuracy for calculation purposes. As it is graphical, though, it is difficult to see how the various quantities affect the performance as a current transductor. It is possible to develop some approximate relations that will give the secondary current mathematically, and will give a different viewpoint to the problem.

It is assumed the circuit is as in Figure 1(B). The d-c saturation curve will be assumed to be two straight lines, as shown in Figure 17. The figure shows the characteristics for one core. This analysis will use the artifice of the previous paper[1] of the reduced saturation curve. Referring to Figure 17, the actual saturation curve is assumed to have an initial slope of μ_i, and a final slope of μ_s, with saturation at B_s. The equations for the two portions of the curve are shown on the figure. The artifice then is introduced of the reduced saturation curve, shown dotted in Figure 17, where the initial straight-line portion of the actual curve is subtracted out. Obviously then, H_r, the reduced magnetomotive force, is zero up to B_s, and above B_s is

$$H_r = \left[\frac{B}{\mu_s} + B_s\left(\frac{1}{\mu_i} - \frac{1}{\mu_s}\right)\right] - \frac{B}{\mu_i} = (B - B_s)\left(\frac{1}{\mu_s} - \frac{1}{\mu_i}\right)$$

It is now possible to quite simply find the d-c magnetomotive force for a particular value of B_0, the d-c flux in the core, for the H_r curve; as H_r is zero for values of flux less than B_s. This was explained in the main part of this paper. The actual value we desire, though, is

$$H = H_r + B/\mu_i = H_r + \frac{1}{\mu_i}(B_0 + B_m \cos\theta)$$

The added portion consists of a pure d-c component and a pure a-c component. The d-c component means there will be an increase in the required d-c excitation. The a-c component will mean there will be an increase in the alternating current. For the opposite core, exactly the same increase in d-c excitation will be required, and an added alternating current will flow in the secondary in exactly the same phase position and magnitude as the above core. The two currents then will add for the total secondary line current.

The principle quantity that is not known is the value of B_0, the d-c biasing flux. As the added direct current due to B_0 is small, it is not needed to know B_0 too accurately, so this approximation will be made

$$B = B_0 + B_m \cos\theta = B_0 + B_m - B_m\frac{\theta^2}{2}$$

This is a good approximation in the range over which θ will be used, from $-\pi/2$ to $+\pi/2$.

$$H_r = (B - B_s)\left(\frac{1}{\mu_s} - \frac{1}{\mu_i}\right) = \left(B_0 + B_m - B_m\frac{\theta^2}{2} - B_s\right)\frac{1}{\mu_s}$$

Let

$H_r = 0$ when $\theta = \phi$

then

$$B_0 = B_m\frac{\phi^2}{2} + B_s - B_m$$

$$H_r = \frac{B_m}{2\mu_s}(\phi^2 - \theta^2)$$

$$H_{dcr}2\pi = \int_{-\phi}^{+\phi} H_r d\theta = \frac{2B_m\phi^3}{3\mu_s}$$

Figure 17. Two straight-line excitation curve and reduced excitation curve for parallel-connected current transductor

$$\phi = \left(\frac{3\mu_s H_{dcr}\pi}{B_m}\right)^{1/3}$$

$$B_0 = B_s - B_m + \left(\frac{3\pi}{2}\right)^{2/3}(\mu_s H_{dcr})^{2/3}B_m^{1/3}$$

$$= B_s - B_m + 2.33(\mu_s H_{dcr})^{2/3}B_m^{1/3}$$

as μ_s and μ_i are very nearly equal.

H_{dc}, the actual primary d-c mangetomotive force becomes

$$H_{dc} = H_{dcr} + \frac{B_0}{\mu_i}$$

$$H_{dcr} = H_{dc} - \frac{1}{\mu_i}\left[B_s - B_m + 2.23(\mu_s^2 H_{dcr}^2 B_m)^{1/3}\right]$$

For all practical purposes, H_{dcr} will be equal to H_{ds}, and H_{dc} can be used in place of H_{dcr} in the right-hand side of the foregoing expression.

The average value of the a-c magnetomotive force based on the line current is twice H_{acr}. To this must be added twice the average value of the added a-c magnetomotive force due to the initial slope of the saturation curve.

The total line magnetomotive force would be

$$H_{tot} = 2\left\{H_{dc} - \frac{1}{\mu_i}\left[B_s - B_m + 2.23(\mu_s^2 H_{dc}^2 B_m)^{1/3}\right]\right\} + 2\frac{2}{\pi}\frac{B_m}{\mu_i}$$

$$= 2\left\{H_{dc} - \frac{1}{\mu_i}\left[B_s - \left(1 + \frac{2}{\pi}\right)B_m + 2.23(\mu_s^2 H_{dc}^2 B_m)^{1/3}\right]\right\}$$

If it is assumed that the two straight-line a-c saturation curve shown in Figure 8 is the same as the d-c saturation curve, and that the same remarks made concerning this curve under the series analysis apply, the following would be true

$$\mu_i = \frac{X_i 10^8}{\omega 0.4\pi N_s^2 A}$$

$$\mu_s = \frac{X_s 10^8}{\omega 0.4\pi N_s^2 A}$$

$$B_m = \frac{\sqrt{2}E10^8}{\omega N_s A}$$

$$B_s = \frac{\sqrt{2}E_s 10^8}{\omega N_s A}$$

$$H_{dc} = \frac{0.4\pi N_p I_{dc}}{l}$$

$$H_{acl} = \frac{0.4\pi N_s I_{acl}}{l}$$

Substituting these in the expression for H_{acl}

$$I_{acl} = \frac{2N_p I_{dc}}{N_s} - \frac{2}{X_s}\left[\sqrt{2}E_s - 2.32E + 2.5X_s^{2/3}\left(\frac{N_p I_{dc}}{N_s}\right)^{2/3}E^{1/3}\right]$$

This is good only as long as the angle of current flow is less than π radians. Substituting the above quantities for μ_s, H_{dc}, and B_m in the equation for ϕ

Figure 18. The 75,000-ampere transductor as installed on the d-c bus

The transductor opening is 11 by 34 inches

$$\phi = 1.88\left(\frac{X_s N_p I_{dc}}{N_s E}\right)^{1/2}$$

$$\text{If } \phi = \pi/2;\ I_{dc} = 0.583\frac{N_s E}{N_p X_s}$$

The rms currents flowing vary considerably, depending on X_s, the slope of the saturation curve over the knee. Use of the rms currents for metering is impractical; but where it is desirable to know them, they can be calculated from the previous paper.[1] An approximate formula for a one straight-line saturation curve can be deduced and may be of use.

This assumes μ_l is infinite and μ_s is finite, and ϕ is less than $\pi/2$.

$$H = \frac{B_m}{2\mu_s}(\phi^2 - \theta^2)$$

$$\pi H^2{}_{(ac\,l\text{-}rms)} = \int_{-\phi}^{+\phi} H^2 d\theta = \frac{B_m{}^2 4\phi^5}{\mu_s{}^2 15} = \frac{4}{15}(3\pi)^{5/2}\left(\frac{B_m}{\mu_s}\right)^{1/2} H_{dc}{}^{5/2}$$

Substituting the value of B_m, μ_s, and H_{dc} in this, the line current is

$$I_{ac\,l\ rms} = 2\left[I_{dc}\frac{N_p}{N_s}\right]^{3/4}\left(E/X_s\right)^{1/4}$$

It also is possible to find the value of the winding rms alternating current. Referring to Figure 6, the total magnetomotive force for one core is the same as the line magnetomotive force, except the line magnetomotive force has positive and negative lobes, whereas the total magnetomotive force for one core has only one lobe. The rms value of the total magnetomotive force for one core then is equal to 0.707 times the line magnetomotive force. Since the actual a-c winding current has no d-c component, it follows

$$(0.707\ H_{ac\,l\ rms})^2 = H_{acw\ rms}{}^2 + H_{dc}{}^2$$

$$H_{acw\ rms} = \left[\frac{H_{ac\,l\ rms}{}^2}{2} - H_{dc}{}^2\right]^{1/2}$$

This formula applies as long as ϕ is equal to or less than 90 degrees.

This above equation, rewritten in terms of current is

$$I_{acw\ rms} = \left[\frac{I_{ac\,l\ rms}{}^2}{2} - \left(\frac{N_p I_{dc}}{N_s}\right)^2\right]^{1/2}$$

Effect of Series Resistance and Reactance

No attempt is made to develop formulas to take care of the series resistance and reactance. Reference 1 recommends that the series voltage drop be subtracted vectorially from the applied alternating voltage, and performance of the reactor calculated with this voltage. This assumes the current is sinusoidal, which is true if ϕ is 90 degrees. It is probably close enough even if ϕ is less than 90 degrees.

Discussion

Eric T. B. Gross (Illinois Institute of Technology, Chicago, Ill.): Since the authors state in the last paragraph of their conclusions that "the transductor is a new device," I may be permitted to suggest a little modification by changing the words new device into "new name for a not-so-new device."

It so happens that I saw such d-c transformers, as they were called at that time, some 15 years ago during a visit to the shops of the AEG Transformer Works in Berlin, where they were built for commercial applications similar to those described in the paper. W. Kraemer, who was mainly responsible for the first commercial design of these transductors, described this work in a number of papers, two of which are listed below.[5,2]

However, I should think that the new materials which we now have available brought about further improvements, though no changes of the principle of operation, which is still older than the commercial application, and I am wondering if the authors would care to indicate the differences between the transductors of today, and the d-c transformers of the past.

E. C. Wentz (Westinghouse Electric Corporation, Sharon, Pa.): This paper is particularly valuable on account of the complete and quantitative nature of the material given. Admittedly there is a great deal of mathematics in the paper, but the result of this mathematics is very real and practical; one can calculate the exact performance of the transductor from the data given.

Of particular interest is the discussion of the parallel-connected transductor and the demonstration that the output in average current as distinguished from rms is a relatively simple function and calculated very easily.

Of course, the rms current also can be calculated according to the paper, but the difficulty with rms current is that most standard ammeters do not actually read rms current if the wave form is distorted. Average reading ammeters are available in milliampere sizes and can be used with a current transformer. At the present time there are no standard current transformers with milliampere secondaries, and the exact measurement of ratio of such transformers cannot be accomplished on the conventional current transformer test sets; but there seems to be a good possibility that these gaps can be filled in. This would make possible the design, construction, and application of transductors on the same basis as conventional current transformers, and would eliminate the present necessity for calibration of ammeters with transductors.

T. R. Specht and **R. N. Wagner:** In reply to Mr. Gross' comments, relatively, the current transductor is new in this country. There has been little in American literature, and practically no current transductors have been built.

In the current transductor, the quality of the core material does not cause a major change in the characteristics of the device. There are applications, such as magnetic amplifiers and mechanical rectifiers, where the modern core materials with rectangular hysteresis loops are very desirable and have considerable effect on performance.

This is not the case with the current transductor.

A New Dry-Type Insulation for Instrument Transformers

R. A. PFUNTNER
ASSOCIATE AIEE

R. E. FRANCK
ASSOCIATE AIEE

F. R. D'ENTREMONT
ASSOCIATE AIEE

ONE OF the most important functions of instrument transformers is that of insulation. Whether it is a high voltage or a high current that is to be measured, the measurement can be made in a practical manner only if the end device is insulated from the normally high circuit voltage.

It has been considered good practice to use two types of instrument transformer insulation depending on the circuit voltage. In general, above 15,000 volts, liquid-filled designs have been used, while below this voltage the dry or compound-filled construction has been employed.

A new dry-type insulation, a molded butyl compound, has recently been developed. This new insulation possesses many outstanding advantages over former dry-type insulation. The use of molded butyl insulation on a 5,000-volt indoor current transformer is shown in Figure 1.

Present Types of Dry- or Compound-Filled Insulation

Dry Type

Present practice of producing dry-type instrument transformers differs somewhat in detail between various manufacturers, but the basic process is essentially the same for all. The coils are wrapped with a fibrous material in the form of tape or sheets so that a given number of layers of insulation cover the entire surface of the coil. This taping is usually applied to the high-voltage coil and is sometimes repeated to a lesser degree on the low-voltage coil. The coils are then assembled together and the core is placed in position. The complete assembly is dried out thoroughly and vacuum-impregnated with an insulating compound.

Some manufacturers use crepe paper for wrapping the coils and others use varnished cambric or other similar materials. Asphalt compound or varnish usually is used as the impregnating medium.

Compound Filled

Compound-filled transformers are insulated in much the same manner as dry types, except that a metal and porcelain casing is placed around the core and coils and the treatment with insulating compound is done in this casing. As a result, the casing is entirely filled with compound.

New Molded Butyl Insulation

The new butyl insulation is placed around the coils of the transformer by a molding process. The core and coils are assembled together without previously being wrapped with any insulating material. In the current transformer design shown in Figure 1, the low-voltage coils are mounted on the legs of the core. The high-voltage coils are assembled over the low-voltage coils and core with adequate clearance between parts to provide space for the butyl insulation. This complete assembly is given in Figure 2.

The assembly then is placed in the mold which has an internal cavity that will form the outside contour of the transformer. The proper relationship between parts is determined by the mold, which supports the components in such a manner as to provide continuous and homogeneous insulation throughout the transformer. Butyl compound is injected into the mold under controlled pressure and temperature conditions. After curing for the proper time and temperature, the completely insulated transformer is removed from the mold.

Both the new process for insulating instrument transformers, and the butyl compound used in the process, have distinct advantages over former types of hand-taped and impregnated forms of insulation.

Figure 3. Structural representation of natural rubber molecule

The molding process assures machine precision of dimensions, as well as producing a 1-piece homogeneous insulation which completely surrounds the high-voltage winding, fills all the spaces between the windings and the core, and forms a protective coating over the outside of the transformer. Molding also provides a ready means of obtaining an attractive appearance in the finished product.

The special butyl compound used in the process has excellent dielectric properties over a wide range of temperature and humidity, and will withstand many abnormal operating conditions without serious deterioration. It is tough and resilient so that it will withstand the mechanical shocks of high overloads and accidental rough handling without damage to the transformer.

Description of Transformer Butyl Compound

Butyl is a synthetic rubber-like material developed just prior to, and during the war. One major application for this material at the present time is for automobile inner tubes, since butyl holds air extremely well. Another application is for cable insulation; a special compound with excellent electrical properties having been developed for this purpose. The basic gum used in cable butyl is compounded with slightly different fillers to make transformer insulation.

Figure 4. Structural representation of ozone and moisture attack on natural rubber

The basic gum is a co-polymer of polyisobutylene and isoprene, both derived from petroleum. Polyisobutylene is a gum-like material made up of carbon and hydrogen atoms so joined together as to be relatively inactive chemically. As such, it cannot be vulcanized with sulphur or other agents to change the soft gum into a rubber-like product. However, by the addition of 1 to 3 per cent of isoprene, which is vulcanizable, the entire mixture can be vulcanized to impart to it many of the excellent physical properties of natural rubber, without the relative chemical instability of this material.

To understand the chemistry of butyl, let us compare it with that of natural rubber. Natural rubber also is a gum-like material composed of carbon and hydrogen atoms. As represented in Figure 3, these are joined together chemically by valence bonds or links; hydrogen requiring one link to be chemically combined, and carbon requiring four. In natural rubber, the ratio of carbon to hydrogen atoms is five to eight, and these are arranged as shown, in long chains forming very large molecules.

As is illustrated, hydrogen is joined with single links while four links must radiate from each carbon atom. However, there are not enough hydrogen atoms in natural rubber, so two carbons are double linked together. This is a relatively unstable condition, and the addition of another element, such as sulphur, destroys the double link which for the purposes of this paper is shown in simplified schematic form in Figure 3. This chemical change vulcanizes the rubber. As is illustrated, not all of the double links need to be stabilized by sulphur atoms to get proper vulcanization. In fact, if enough sulphur were added to combine completely with all the unstable carbon atoms, hard rubber such as was once used on telephone receivers would result.

Consequently, even vulcanized rubber is relatively unstable, and the addition of other elements such as oxygen or ozone will break up the remaining double links. In this case, as is shown in Figure 4, ozone plus water vapor breaks the structure apart and destroys the rubber properties. Cracking and hardening, usually found in old rubber, are characteristic of this destruction.

Figure 5. Structural representation butyl compound

Butyl gum, on the other hand, does not have this instability. Polyisobutylene, which comprises 97 to 99 per cent of the gum, has no double links, as is illustrated in Figure 5. The 1 to 3 per cent of isoprene, also illustrated in this figure, has the same double links as found in natural rubber. However, practically all of these extra valence bonds are used up in the vulcanization process, so that a remarkably stable material results.

To use butyl gum for insulation, it must be mixed or compounded with suitable fillers to give it increased hardness, and with a small amount of sulphur and other similar agents, to provide for vulcanization. This compounding changes the sticky translucent gum to the opaque vulcanizable material used in the molding of transformers. The vulcanizing process, which produces the tough, flexible insulation of the final product, occurs during the cure, after the butyl has been completely injected into the mold and around the other parts of the transformer.

Figure 6. Tensile strength versus temperature transformer butyl and asphalt paper

Figure 7 (left). Resistance to mechanical damage—transformer butyl and asphalt paper

Figure 9 (right). Power factor versus temperature—transformer butyl and asphalt paper

Characteristics of Butyl Insulation

Before butyl insulation could be used for instrument transformers, its properties had to be evaluated in terms of all the various conditions such insulation is required to meet. These characteristics were determined primarily by laboratory test. Since the first instrument transformer placed in production using butyl insulation was the 5,000-volt indoor current transformer illustrated in Figure 1, the over-all performance of butyl was evaluated by tests on this design. Many individual properties also were evaluated by tests on other designs of current transformers, and on other, simpler test samples. For control purposes, samples of asphalt-impregnated paper insulation of the type presently used on dry-type transformers also were included in the tests.

Physical Properties

The physical properties of both the special transformer butyl compound and the present asphalt-paper insulation are shown in Table I. The tensile strength of both materials varies with temperature. As indicated in Figure 6, the direction of lamination affects the strength of asphalt-paper, while butyl has the same strength in all directions. At the normal top operating temperature of 85 to 95 degrees centigrade, butyl is stronger than the older insulation, although both are adequate for the application.

The elongation of butyl is much greater than that for asphalt-paper, which is a distinct advantage, since the thermal expansion of parts and severe distortion forces caused by high momentary overloads or accidental rough handling will not crack the butyl.

As shown in Figure 7, butyl is much more resistant to mechanical damage than the older style insulation. The depth of penetration listed in this curve is the permanent damage done to the insulation; the depth of the cut in the material after each blow.

Chemical Properties

Comparative chemical properties of transformer butyl and asphalt-paper are listed in Table II. Like most organic insulations, butyl compound is attacked by organic solvents, but its resistance to these materials is much greater than that of asphalt paper.

Toluene, for example, completely dissolved the asphalt from asphalt-paper insulation in six hours at room temperature. Butyl swelled to 65 per cent larger volume and its elongation was reduced from 680 per cent to 100 per cent in one day, and very little further change occurred in three weeks. Thus, while butyl is attacked by toluene, the rate of attack and severity of the result are much less than for the older insulation. Carbontetrachloride and various light oils also gave similar results as indicated in the table.

Acids do not affect butyl appreciably, but do attack asphalt-paper. A 30-per cent solution of sulphuric acid left no visible signs of attack on butyl after three weeks at room temperature. Asphalt-paper, during the same period, lost most of its tensile strength, probably because the paper was attacked by the acid.

Alkalis do not affect butyl but do attack asphalt paper. A 10-per cent solution of sodium hydroxide delaminated the

Dielectric strength versus time at temperature

asphalt-paper insulation in one day, but showed only a slight surface hardening on the butyl after three weeks.

Butyl also is more flame-resistant than asphalt-paper. Both will burn under the right circumstances, but butyl burns much less readily and much slower. A test used by one fire insurance company is to play the hottest part of a bunsen burner flame on the sample for 15 seconds, remove it for an equivalent time, and repeat until the sample continues burning during the entire interval between applications of the flame. Under this test, butyl averaged eight cycles while asphalt-paper continues burning after the first application of flame.

Electrical Properties

Comparative electrical properties of transformer butyl and asphalt-paper insulation are shown in Table III. As may be seen, the dielectric strength is much higher for the new material. However, such factors as the thickness of butyl tested, the thickness of the paper, and thus the number of layers, in the asphalt-paper sample, will affect the absolute value of the result. In general the relationship between both types of insulation will be maintained under all ordinary conditions. The effect of temperature on the dielectric strength of both materials is shown in Figure 8.

The insulation power factor is considerably lower for butyl than for asphalt-paper. Again, the specific design on which these insulations are used may cause the power-factor to vary somewhat from the range indicated which is for the materials above. The power factor of molded butyl is not appreciably changed by variations in temperature or voltage; a distinct advantage. The power factor of asphalt-paper insulation is affected much more as shown on Figure 9.

Stability of Properties with Time and Other Factors

In order to make as complete an evaluation as possible, the ability of butyl to retain its properties under various conditions was investigated.

The effect of time and temperature on the various properties of the special transformer butyl compound is shown in Figures 10 through 13. As shown on Figure 10, butyl at 121 degrees centigrade remains elastic for a much longer period than long-life natural rubber of the type used for cable insulation. Since the normal operating temperature is under 100 centigrade, this test represents an accelerated condition. The change in tensile strength, as shown on Figure 11, also

*Dielectric strength tests made on 1/8-inch thick samples. Voltage applied in 5-kv steps each of one minute duration.

is very small in the operating temperature range. Other physical properties, such as elongation and elasticity, exhibited a similar change with time and temperature.

Because these tests were made on thin sheets of butyl there appears to be an aging effect. Additional tests have shown that the deterioration of the material is a surface effect, working from the outside in. Complete transformers, for example, exhibited signs of cracking and deterioration on the surface after 1,500 hours at 150 centigrade. However, dissection of the transformers after test showed that good solid butyl existed 1/16 to 1/8 inch beneath the surface, and thin sheets cut from these inner sections showed normal values of hardness and elongation, and a 30 to 50 per cent reduction in tensile strength from initial values. Thus, the changes in the sheets which

Figure 14. Transformer butyl sheets: effect of exposure to 90 per cent relative humidity at 35 degrees centigrade

occurred at even 150 centigrade are interesting data, but are not significant from the standpoint of the transformer life.

Electrical properties, such as dielectric strength and arc tracking, show no change with time and temperature as indicated on Figures 12 and 13.

Although the new transformer design is for indoor applications only, the effect of humidity and simulated outside weathering conditions on butyl was investigated. Figures 14 and 15 show that continuous exposure to high humidity raises the power factor somewhat, but weatherometer conditions do not change this property significantly. Again these tests were made on thin sheets where the surface effect greatly exaggerates the changes.

Since a small amount (approximately 0.5 per cent) of sulphur is needed to vulcanize the transformer butyl, the possibility of the molded insulation corroding the copper parts of the transformer was investigated. Figure 16 shows typical time versus resistance curves for very small wires molded in butyl and exposed to various temperature and humidity conditions. As indicated by the flattening of the curves, the corrosive effect becomes negligible after a short period of time, probably because all the sulphur compounds in the butyl adjacent to the copper are used up, and the rate of additional sulphur penetration to this area is extremely slow.

Corrosion data for various sizes of wire, temperatures, and amounts of sulphur in the butyl are shown in the Graeco-Latin squares of Figure 17 for tests in air and water vapor. The notation, 100% S, indicates the amount of sulphur (approximately 0.5 per cent) used in transformer butyl. Other amounts, varying as shown from this normal value, were milled into the butyl for the other samples.

The percentage figure shown in the center of each square (1%, 4%, 12%, and so forth) indicates the ultimate increase in resistance as shown for typical examples on Figure 16. Under the worst condition with the normal amount of sulphur (100% S), a 3 per cent increase in resistance was noted. Since a 10 per cent increase represents only a 0.00025-inch penetration in 0.010-inch diameter wire, the corrosive effect of butyl on copper is negligible. The fact that wire sizes normally used in instrument transformers are considerably larger than those used in this test further reduces the significance of corrosion as a factor in transformer life.

Figure 15. Transformer butyl sheets: effect of exposure in weatherometer

Ionization Characteristics of Butyl

The foregoing data indicates that butyl has very excellent properties as a transformer insulation, and that these properties may reasonably be expected to remain constant for long periods of time under the many conditions of use to which transformers might be exposed. However, any insulation material will fail in a relatively short time if it is operated continuously at too high a voltage stress, even though this stress is considerably below the short-time dielectric breakdown value. The importance of this phenomena has warranted the investigation of many types of material by various methods. In general, the most widely accepted method is that of determining the amount of ionization present at the operating voltage.

As applied to electrical insulation materials, ionization is commonly thought of as a phenomenon resulting from the bombardment of molecules by particles of atomic or even smaller dimensions. When the voltage stress is high enough these particles are accelerated to a point

Figure 16. Corrosion of bare copper wire molded in transformer butyl

Typical time versus resistance curves

where they can free electrons from the molecules of the insulation material and cause ionization.

If no ionization is present at the operating voltage, almost infinite life can be expected. Test samples with round electrodes have operated at 125 volts per mil continuously for 120 days with no deterioration indicated. This life, at a stress in excess of five times that used in transformers, is possible with this type of sample because there is no ionization below approximately 175 volts per mil.

Tests on several hundred transformers of the 5,000-volt design illustrated in Figure 1 have shown that ionization does not start until a voltage well above 5,000 volts is reached, and stops above this value when the test voltage is reduced. Without ionization at the operating voltage, there is no cause for electrical deterioration. This fact, plus the chemical and physical stability of transformer butyl, makes it an ideal dry-type insulation.

Conclusion

1. A new solid insulation useful for voltages presently handled by instrument transformers made with dry-type insulation has been described. This insulation, molded butyl, has been applied to instrument transformers and represents a significant advance in the design and manufacture of these devices.

2. The properties of molded butyl compound are significantly better than those of older insulation, both in initial characteristics, and long time stability under adverse operating conditions.

A Primary Method of Measuring the Ratio and Phase Angle of Current Transformers

ALLAN L. BROWNLEE
ASSOCIATE AIEE

A METHOD of measuring the ratio and phase angle of current transformers has been developed to extend the range of the present current transformer testing apparatus to higher current values.

Shunts with a top range of 2,500 amperes now are used. Since 2,500 amperes is about the top limit for an a-c shunt, either a multiturn primary transformer had to be used, or some other method employed.[1] Tests indicate that mutual inductors are practicable, inexpensive, and have an accuracy comparable to shunts for a direct calibration of current transformers in all current ranges.

The use of ring solenoids in the place of shunts for the calibration of current transformers is not new. In 1915 Charles Fortescue described a method of calibration in which carefully distributed windings were wound on accurately machined marble cores.[2]

The method developed here is similar to the Fortescue method but has two important differences, the solenoid design and the method of calibration, and is based on three fundamentals:

1. The magnetic flux in any closed nonmagnetic path is a function of the interlinking ampere turns and the reluctance of the path, and is independent of the size or position of the interlinking convolutions.

2. The magnetic flux in the closed path has a fixed relation both in magnitude and phase to the current that produces it.

3. The voltage induced in a plane loop is proportional to the vertical component of the flux threading it.

The flux induced in the core of the ring solenoid, Figure 1(A), by interlinking ampere turns, not shown in the figure, is independent of the size and position of the interlinking convolutions, but is dependent on the dimensions of the core (reluctance of the path).

The voltage induced in a loop around the core is proportional to the component of flux tangential to the axis of the solenoid if the loop is in the plane of the axis. The voltage generated in a series of such loops spaced on the core of the solenoid measures the tangential components at corresponding points on the core and approaches a true measure of the flux in the core as the loops are increased.[3]

The series connection of the loops must be so arranged that, as G. A. Campbell pointed out in his discussion of the Fortescue paper,[4] the connections do not form a loop around the axis of the ring. The connections used to eliminate this loop are shown in Figure 1(B). Two such solenoids can be compared by using a series current in the interlinking turns of each solenoid and then with an appropriate change in the interlinking turns again compared one in the primary and one in the secondary of a current transformer.

When so compared, the following relationship holds for small phase angles.

$$R = \frac{NcpNs}{NcsNp}(1 \doteq b \doteq a)$$

R = true transformer ratio
Ncp = interlinking turns, primary solenoid series comparisons
Ncs = interlinking turns secondary solenoid series comparison
Np = interlinking turns primary solenoid test
Ns = interlinking turns secondary solenoid test
b = constant difference determined by series comparison
a = difference determined by test

The phase angle is

$$\theta = \tan^{-1} \frac{r}{\omega M(1 \doteq b \doteq a)}$$

r = resistance introduced into the test to compensate for the phase angle of the current transformer
M = Mutual inductance of secondary solenoid (calculated)

The usual corrections can be made where the phase angle causes appreciable error.

Since mutual inductance does not appear in the ratio formula the only requisite is that, as affected by the ring solenoids, it remain constant between comparison and test.

The accuracy of the method was tested on a 1,500-to-5-ampere current transformer checked by the National Bureau of Standards. The results of this test are shown in Table 1; the ring solenoids in Figure 1; and the schematic diagram of connections in Figure 2.

The ring solenoids were built of laminated wood, turned on the face plate of a lathe in halves, with a semicircular core cross section, and doweled together to form the finished ring. With the dimensions and turns shown in Figure 1(A) the voltage induced in solenoid P is about 1.1 volts when excited by 1,500-ampere turns, and the voltage induced in S is the same when excited with 500-ampere turns 60 cycles.

The developed winding also is shown in Figure 1(B). Each turn of the single layer winding was wound in the plane of the ring axis, and the connections between turns were twisted to eliminate a loop around the axis. The wire size was number 30.

For the calibration the two ring sole-

Figure 2. Connections for current transformer calibration

(a) Series comparison of two ring solenoids
(b) Test connections after solenoids have been calibrated by series comparison

noids were compared as shown in Figure 2(A). Solenoid P was interlinked with three turns, S with one turn. The current was 500 amperes. Exact balance was obtained by separating the appropriate core with equally spaced wedges. This adjustment reduced the constant b in the ratio equation to zero. Solenoid S then was compared with the inductometer A using 1-to-5 turns on S with 5-ampere series current and balancing the inductometer against S to calibrate the inductometer in terms of a in the ratio formula.

For the transformer calibration, connections shown in Figure 2(B) were used, with one turn on P and 100 turns on S, and balance was obtained for the various current values. Then

$$R=\frac{3.100}{1.1}\ (1 \doteq a)$$

$$\theta=\tan^{-1}\frac{r}{0.221(1 \doteq a)}$$

The balance was stable with a null detector sensitivity of about 0.0001 volt and an impedance of one megohm. No shielding was used, and no effort was made to reduce the size of external loops, but the interlinking convolutions were approximately the same size and in the same position on the solenoids for the series comparison and the test.

To determine the effect of size and position of interlinking convolutions, a ratio and phase angle balance was made with 1,500-amperes primary current, with the single turn through the solenoid P centered and the return loop about four feet distant from the solenoid. This loop then was closed to about six inches and balances obtained for eight positions around the ring; these data are shown in Table II.

The differences shown at the various locations of the small loop around the ring are due to variations in the core diameter and the resulting change in the area of the corresponding turns. A straight centered turn averages these differences. The differences do not enter as errors in the calibration if the size and position of the interlinking convolutions is the same for the series comparison and the test.

To determine the effect of external field the voltage induced in the solenoid P was measured when a 15-inch loop carrying 1,500 amperes, 60 cycles was placed at various locations with respect to the solenoid, but not interlinking with it. The maximum voltage measured was 0.0035 volt when the plane of the loop was perpendicular to the ring axis and symmetrical with it. For all other positions the induced voltage decreased and when parallel to the axis was less than 0.001 volt.

The work done is preliminary to the final design. Ring solenoids of a more suitable material than wood will be carefully machined to calculated dimensions and slots milled to position the detecting winding. Instead of changing dimensions with wedges to exactly balance in the series comparison the difference, factor b in the ratio formula will be determined. With stable material in the core of the ring the frequency of the series comparison tests should be comparable with the shunt calibrations in the present current test apparatus, about once a year, and the factor b comparable to the corrections applied to shunts.

A comparison of the data in Table I indicates that with carefully machined cores of suitable material accuracies of 0.01 per cent in ratio and one minute in phase angle can be obtained.

Relay Protection for Medium Length High-Voltage Transmission Lines

J. H. KINGHORN
MEMBER AIEE

PROTECTIVE relaying development over the years has produced a wide choice of equipment varying from simple instantaneous current types to more complicated directional and impedance types. The ingenuity of relay engineers has produced a still wider choice of methods of applying the various types of relays which are available. It is the purpose of this paper to discuss the various types of relay protection which are applicable to medium-length high-voltage lines and, using a typical system as an example, examine some of the advantages and disadvantages which are inherent in them. Companion papers[1,2] treat the protection problems for long and short lines. In order to limit the discussion to reasonable length it will be confined to types of relaying available as standard equipment, although the possibility of special schemes for special purposes must be recognized.

Description of Typical System

Figure 1 shows a hypothetical system selected to represent a range of conditions frequently encountered. It is assumed to be a predominantly steam-driven system where transmission line loading can vary considerably depending upon the location at which power can be generated economically or upon what generating units are out of service for either scheduled or emergency maintenance. The system is simplified to the extent that elements not essential to the problem of protective relaying have not been shown.

The lines from station A to stations G and C are respectively 40 and 50 miles long and are typical medium-length lines. They have to meet sufficiently similar conditions so that their required relay protection is identical. The discussion will therefore be confined to lines AL to G.

Figure 2 shows a typical heavy loading condition on these lines such as can be expected with generators at B and C out of service. It represents about as heavy power transfer as can be expected from station A to stations G and C for any except emergency conditions. Figure 3 shows 3-phase short-circuit values for the various station busses.

Transient as well as steady-state conditions must be considered. A permanent 3-phase fault on lines AL to G during which they are tripped, reclosed high speed and retripped would represent about as severe a condition as the relays on lines AR to C might be called on to handle. Figure 4 shows the power-angle-swing curves for this condition with the heavy initial loading of Figure 2. Figures 5 and 6 show the impedance seen by relays at the two ends of the line during the oscillations caused by such a fault. The circles represent suggested relay operating point loci as will be discussed in this paper.

General Objectives

The objective will be to provide the best type of relaying available with ability to meet all expected conditions being given first consideration and cost being taken into account after technical requirements have been met. This is considered justified by the importance of the four lines in question which under certain conditions are expected to carry a total of about 300,000 kw, Figure 2. This relaying must be reliable and fast in operation. It must be capable of clearing minimum fault currents expected and at the same time must be capable of carrying the heaviest load currents and transient swings without false tripping.

General Advantages Gained by Employing One-to-Two-Cycle Relaying

The advantages of obtaining the fastest possible tripping time for faults at any point on the protected lines are well known. Those most commonly mentioned are:

1. Reduction of short-circuit damage with consequent increased chance of re-energizing the line immediately.
2. Minimization of the objectionable effects of voltage dips on customer's motors.
3. The ability to carry higher loads without loss of synchronism because of short circuits.
4. The ability to employ ultrahigh-speed reclosing (20 cycle or less) and so increase the maximum loading which can be carried safely.

Pilot wire or carrier relaying schemes must be employed to obtain this speed for they are the only types of relaying currently available which do not require graded time settings to insure selectivity with relays on adjacent line sections. Without examining the problem in detail it is evident that the line lengths involved make pilot wire relaying uneconomical and it will therefore be disregarded.

Extent to Which One-to-Two-Cycle Relaying Advantages Are Realized on Typical System

For lines as heavily loaded as these the ability to re-energize immediately after a flashover is of considerable importance. The loss of one line produces heavier loading on the remaining three, and although these lines are capable of carrying this loading, the increased line losses and poorer voltage regulation at inter-

Paper 50-68, recommended by the AIEE Relay Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted October 31, 1949; made available for printing December 2, 1949.

J. H. Kinghorn is with the American Gas and Electric Service Corporation, New York, N. Y.

Figure 1. Typical system; positive sequence impedance per cent on 138,000-kva base

Figure 2. Heavy loading condition on lines *AL* to *G* and *AR* to *C*

mediate stations might be sufficiently objectionable to make necessary a reduction in the amount of power interchange. These objectionable conditions could be minimized still further if ultrahigh-speed reclosing were employed, because in about 90 per cent of the cases it would permit the line to be restored to normal before any objectionable voltage conditions could appear on the system. The advantages of reclosing at once are even more pronounced if one line is assumed out of service and a fault occurs on the second line.

Faults on an extensive high-voltage system of this sort are reflected usually in in voltage dips over a considerable geographical area which may affect service to a large number of industrial customers. While modern practice provides time delay undervoltage protection for industrial motors to prevent their loss during momentary voltage dips, there are sometimes heavily-loaded synchronous motors which can lose synchronism during relatively minor system disturbances. High-speed fault clearing helps to prevent this loss of synchronism. Data are not included for a detailed analysis of the system under consideration and generally such analyses are not worth while unless inspection discloses cases which may be critical. There usually are some such individual instances, but their extent and importance cannot be evaluated here.

A transient stability study of the system, Figure 4, shows that a double-line 3-phase fault at *AL* on the lines from *AL* to *G* can be tripped, reclosed into the fault in 20 cycles, and retripped without loss of synchronism over lines *C* to *AR*. This shows the system to be quite stable under heavy load and severe fault conditions, and demonstrates that from this standpoint 20-cycle reclosing is unnecessary. However, it further shows that 20-cycle reclosing will not be instrumental in causing loss of synchronism when reclosing into a permanent fault.

Carrier-Current Relaying

These considerations lead to the conclusion that carrier relaying is justified and should be installed on these lines for the increased chance it offers of avoiding prolonged line interruptions and therefore avoiding the poorer voltage regulation and increased transmission losses which such interruptions produce in the rest of the system. Furthermore, with carrier relaying installed, ultrahigh-speed reclosing can be employed at practically no additional cost and should be used for the same reasons. Further justification is found in the improvement of customer's service and in the increase in permissible loading limits which may be of value under possible emergencies or as loads grow in the future.

Carrier relaying, in common with any other type, must be capable of tripping under minimum short-circuit conditions. Furthermore if maximum speed of fault clearing is to be attained this minimum must be determined with both ends of the line closed to avoid sequential tripping. The fault detector relays should not pick up under maximum load conditions because this would cause continuous carrier transmission. This is considered objectionable because of possible interference with other carrier channels. Tripping relays must not pick up because, while incorrect tripping would not result as long as carrier transmission continued, there is always danger of it if any momentary interruption to transmission or reception should occur. Keeping these limitations in mind, phase comparison and directional comparison using impedance-type relays, which are the two types of carrier relaying in common use, will be considered.

Phase Comparison Carrier

Phase comparison is essentially a simple overcurrent type of relaying in that its tripping and carrier starting points are determined entirely by current measurement. Considering the lines from *AL* to *G* the maximum indicated load is about 430 amperes, and if one line were out it would probably be above 600 amperes. For a 3-phase short circuit at *AL* with the system normal, 990 amperes flows over each line from *G*, Figure 3. To insure that carrier not be transmitted continuously, the starting relay should have a pickup not lower than 600 times 1.5 = 900 amperes. If it is considered that this loading is of sufficiently infrequent occurrence as to be neglected then the starting relay can be set at 430 times 1.5 = 645 amperes. The tripping relay should be set at least 25 per cent above the starting relay to insure co-ordination which gives at least 806 amperes. This value is dangerously close to the minimum short-circuit value of 990 amperes and leaves no margin for the further reduction of this value which will occur when system conditions are abnormal. Furthermore, there is no chance of handling heavier loads, should they develop. If a negative phase-sequence network were employed, the setting would become independent of load current, but the relay would then be incapable of operation on 3-phase short circuits. For these reasons phase comparison carrier relaying does not appear adequate.

Figure 3. Three-phase fault distribution in megavolt-amperes

Figure 5. Impedance locus seen by relays on lines *AR* to *C* at *AR* for simultaneous 3-phase faults on lines *AL* to *G* near *AL*

Directional Comparison Carrier

Directional comparison carrier relaying using conventional reactance or impedance-type relays for carrier starting and tripping will avoid some of the objectionable features of a simple overcurrent scheme. For discussion purposes an impedance type relay will be considered. Line *AL-G* has an impedance of about 24 per cent. It is generally considered conservative practice if the carrier tripping relay impedance setting be made 50 per cent higher than the line impedance, which would be 36 per cent. The carrier starting relay impedance should be at least 25 per cent higher than the tripping relay, which would amount to about 45 per cent. This setting would correspond to about 1,280 amperes at normal voltage, which is an adequate margin over the maximum expected load current of 600 to 700 amperes. It therefore appears that directional comparison using impedance-type relays can adequately protect against minimum faults and still handle maximum loads without incurring continuous carrier transmission.

By a similar method of analysis it can be shown that reactance-type relays also will give satisfactory results. It is obvious, therefore, that the mho- and modified-impedance-types also would cover the conditions with probably an even greater safety margin.

The ground relaying for carrier should be provided with a separate ground directional relay, either current or potential polarized, and arranged in the conventional way to provide ground preference type of operation. This is necessary to avoid any possible incorrect operations which might be caused by the effect of load currents on the action of the phase directional relay during ground faults. As in the case of the phase relays, the ground-tripping relay should be sufficiently sensitive to insure tripping on minimum ground faults, and it is suggested that the pickup be not higher than one-third of the minimum calculated ground fault to provide a reasonable safety factor for possible impedance at the point of fault. Furthermore, it is desirable that at minimum calculated fault currents the relay operating time be at least as short as that of the phase relays under phase-to-phase faults, and that this time be about the same at both ends of the line even though the fault currents at the two ends differ materially, so that ultrahigh-speed reclosing can be successful. If ground-directional relays having an operating time which varies with torque are used it may be necessary to make the setting even more sensitive than the value suggested previously to insure that, at minimum fault currents, operation is on the flat part of the timing curve.

Phase-Backup Relaying

Although the primary carrier relaying can be expected to clear all faults in the protected line section under normal conditions, backup relaying is still required for a number of reasons. There are times when the carrier must be taken out of service for repair or calibration. Occasionally conditions arise, such as sleet formation on the conductors, when the carrier signal cannot be received. If an oil circuit breaker should fail to trip on a faulty line section, some means is needed for tripping adjacent sections. Tie lines between generating stations sometimes must be tripped under out-of-step conditions. Backup relaying must be provided to obtain as many of these features as possible.

Figure 4 (left). Power-angle swing curves, simultaneous 3-phase faults on lines *AL* to *G*, both lines reclosed and retripped

Figure 6 (right). Impedance locus seen by relays on lines *AR* to *C* at *C* for simultaneous 3-phase faults on lines *AL* to *G* near *AL*

The choice of backup relaying may be influenced by the type employed generally on the system. It must co-ordinate properly with the relays on the adjacent lines. Generally speaking impedance- or reactance-type relays can be made to work successfully with inverse-time-induction types and it will be assumed that this can be done in this case. Whatever type is chosen should be designed to clear faults as fast as possible while still retaining adequate selectivity with backup relays on adjoining line sections. Impedance- or reactance-relays with definite time settings and induction overcurrent combined with plunger-type instantaneous overcurrent will be considered.

Three-Step Impedance Relaying

Impedance-type relays with the conventional 3-step arrangement for phase protection would be subject to the same limitations in sensitivity and load-carrying ability as those outlined for carrier relaying. For the lines from AL to G at AL the first, or instantaneous, tripping zone could be set to cover about 90 per cent of the line. The second zone must have a time setting selective with the protective relays on the other outgoing lines and with any time delay transformer or bus differential relays at G. The worst condition would probably be selectivity with the relays on the line from G to E. The total line impedance from AL to E is about 30 per cent, which is only about 25 per cent greater than the impedance of line AL to G. If the second zone setting is not to reach beyond E this would give an impedance setting with a rather narrow safety margin. However, with the system normal and a fault at E the apparent impedance seen by the relays at AL is much higher than 30 per cent. Even with one line out from AL to G this is true because of the effect of the lines from G to C. Furthermore, it is assumed that line GE will have carrier or pilot wire relaying for primary protection so that its relay time will normally be one to two cycles and that all lines out of E will have 1-cycle relaying for faults near E. Since it is unreasonable to assume that the second line from AL to G and the lines from G to C will all be out at the time when a fault occurs close to E which the fast relaying of E or the pilot wire relays on GE fail to clear, it is justifiable to make the impedance setting at AL at least 35 per cent, which gives a 50 per cent safety margin for faults near G. A study should be made to make sure this does not overreach E with the second AL to G line out.

The third zone setting, which would correspond to the carrier starting relay, could be set for an impedance of 48 to 50 per cent as outlined for the carrier relaying which would be well below maximum load impedance as well as below maximum impedance seen by the relays during a transient swing. This transient swing condition has not been analyzed accurately, but it may be estimated by examining Figure 5 which shows the conditions on lines AR to C for permanent trouble on both lines from AL to G with 20-cycle reclosing. A similar analysis can be employed for the relays at G except that in this case the third zone impedance setting cannot be made high enough to reach to station J with the system normal, and any backup protection to cover oil circuit breaker or relay failure of AL would have to be provided by some scheme installed at station AL.

Simple Overcurrent Relaying

If time-delay induction overcurrent combined with plunger-type instantaneous relays were employed on AL to G their limitations would be similar to those outlined for phase comparison carrier. The instantaneous relays at both ends could easily be set to cover 90 per cent of the line length. At G their tripping would have to be controlled by a directional relay. The time-delay relays at both ends would have to be set above 900 amperes to prevent operation on heavy load currents with one line out. However, it is not necessary that they operate on minimum fault conditions with all lines in but merely that they operate with a reasonable safety margin after the opposite end has opened.

For a fault at the end of one line to G the current from AL would be about 2,000 amperes after the circuit breaker at G has opened. Since this is based on maximum generating conditions and on all lines being normal except the one in trouble, it is a rather narrow safety margin over the 900-ampere pickup setting. A voltage control scheme might be introduced which would prevent the overcurrent relays from operating unless the voltage dipped, thereby permitting the current pickup to be reduced to about 600 amperes. For the same fault condition the voltage at AL would be about 80 per cent and the voltage control device would have to be set to drop out at 90 per cent, which is dangerously close to the normal operating point. This narrow margin might be tolerated but future expansion would reduce it still further and it appears preferable at AL to employ impedance relays where a satisfactory margin exists.

For a fault at the end of one line to AL from G the current at G would be about 1,600 amperes with the circuit breaker at AL open. This is again an inadequate margin over the pickup setting of 900 amperes. However, in this case voltage control could be used satisfactorily since the voltage at G would dip to about 65 per cent. Directional control also could be used since normal heavy power flow is always from AL to G. Either scheme has the advantage of providing a backup relaying scheme independent of the carrier relaying. Since a directional feature is required with the backup relaying at this point the carrier directional relay could be common to both schemes if desired and would result in some reduction in cost. Voltage control is suggested in this case primarily because the same voltage relays can be used for the other lines at the station and it therefore will be the more economical setup.

Ground-Backup Relaying

For ground relaying at AL an instantaneous, plunger-type relay can be employed set to pick up at about 105 to 110 per cent of the ground current in the line for a fault at G with the parallel line out. An induction overcurrent relay set to pick up at about one-third of this same short-circuit current can be used to cover faults below the pickup of the instantaneous relay. The pickup value of one-third of a solid fault at the far end of the line should be ample to cover any high-impedance grounds which might be encountered. A product-type relay polarized by zero sequence voltage or transformer neutral current might be used instead of a simple overcurrent relay. Since a directional feature is not required at AL it would have no advantage except to reduce somewhat the impedance in the bushing current transformer circuit, which is not essential.

For ground relaying at G both the instantaneous and the time-delay relays would need to include a directional feature. This could be provided by the directional relay in the carrier set if desired or a product-type time-delay relay could be used. The product-type relay has the advantage of providing a backup relay entirely independent of the carrier relays but is sometimes hard to co-ordinate on a line having ultrahigh-speed reclosing.

Balanced Protection

Since the two lines in question have equal impedance and terminate on common busses at each end, it would be pos-

sible to employ balanced protection phase and ground relays at both ends. These compare the currents in the two lines and operate to trip the line in trouble when its current exceeds that in the other line by a predetermined amount or percentage. Power directional measurement is included at stations not a source of short-circuit current. Since there is no problem of selectivity with relays on adjacent line sections they can be instantaneous in operation. They would operate in one to two cycles for single-circuit faults over 80 to 90 per cent of the line and for the remainder of the line would operate sequentially after the other end had tripped. They also would operate for some cases of simultaneous trouble on different phases of the two lines when the impedance relays might measure a false impedance. For single-line phase-to-phase faults beyond the instantaneous zone of the impedance relays they should shorten the total clearing time because, even with sequential tripping, the total time would probably be shorter than the time of the second zone of the impedance relays. For ground faults in a similar location sequential instantaneous tripping would probably occur from the instantaneous ground relays, because there is an increase in ground current after the near end has tripped which will permit the relay at the far end to pick up. Similarly for simultaneous faults on different phases of the two lines there is a good chance that the instantaneous ground relays will operate, even for the infrequent case when these faults do not involve ground.

It appears therefore that tripping time is shortened only for phase-to-phase faults in the last 10 per cent of the line which is 20 per cent of the faults not involving ground. If 90 per cent of the faults involve ground (this depends on line construction and other physical factors), then improvement is obtained in only 0.10 times 20 per cent = 2 per cent of the total cases of trouble. Since the improvement obtained of perhaps 0.3 second faster clearing is not a critical factor in system performance and the cases of trouble covered are so few, it is doubtful whether these relays are justified. When carrier relaying is used as primary protection the value of balanced relaying becomes insignificant.

Relative Costs

In order to give some idea of the relative costs of the various types of relaying discussed, the installed cost of directional comparison carrier using impedance or reactance relays has been assumed to be 100 per cent. This includes the capacitor, transmitter-receiver, line trap, relays, cable for transmitter-receiver, installation labor, and overhead. The relay setup available as standard equipment includes impedance backup and any type of ground backup required. On this basis the installed costs of other type would be approximately as shown in Table I.

Table I

	Per Cent
Modified-impedance or mho-type carrier	100
Phase Backup	
Added cost for 3-step impedance backup (phase only)	0
Added cost for time and instantaneous overcurrent with voltage control and using carrier phase directional relay	6
Added cost for directional controlled phase overcurrent using self-contained single-phase directional relays and instantaneous overcurrent controlled by carrier directional relay	8
Ground Backup	
Added cost for time and instantaneous overcurrent ground relay	0
Added cost for product type time and instantaneous overcurrent ground relay	0
Balanced Protection	
Added cost for high-speed current balance relays	11

These figures indicate that if a standard carrier relaying setup is purchased, a small additional premium must be paid to obtain a phase backup arrangement using relays separate from those employed for the carrier. However, it is possible to employ special relays for carrier which have only the features which are needed for the carrier functions at a considerably reduced cost. This can be combined with separate 3-step impedance backup at a total cost about 3 per cent higher than that of a standard setup. In any case the relaying is a small proportion of the total value of the line being protected, and is even a small proportion of the cost of the remaining terminal equipment such as circuit breakers and disconnect switches. Once carrier relaying has been decided on, the choice of backup protection on important lines can be based almost entirely on technical considerations. Further, the relatively small cost of carrier as compared with the equipment and service which it protects makes its selection likewise dependent primarily on the technical advantage which it offers on important lines. Since the dollar cost of carrier goes down only a small percentage on lower voltage lines and that of backup relays not at all, economic factors assume greater importance as the voltage and importance of the lines involved decreases. From this standpoint there is an important field of development open for relaying schemes including carrier, which will provide high-speed accurate tripping at sufficiently reduced cost to justify their use on low-voltage lines.

Conclusions

A summary of relay protection which has been suggested is as follows:

Primary Protection

Directional comparison carrier current relaying using impedance-type phase relays and ground preference scheme.

Backup Protection

At AL and AR

Phase protection, 3-step impedance relays.

Ground protection: simple instantaneous plunger relays and inverse time induction relays.

At G and C

Phase protection: simple instantaneous plunger-type relays, inverse time induction overcurrent relays with voltage control, using the carrier directional relay.

Ground protection: simple instantaneous plunger-type and inverse time overcurrent relays using the carrier directional relay.

The elements available for building up an adequate protective scheme have multiplied and improved as the needs have grown and we have every right to expect that this progress will continue. Advantage of special arrangements to cover special situations must always be taken by the relay engineer, but in making such applications the effect of changing conditions due to system expansion must always be kept in mind. These suggestions are based on standard equipment available from manufacturers which is suitable for the typical system involved and will accomplish the objectives of fast, reliable protection insensitive to maximum load currents and transient swings.

Discussion

A. J. McConnell (General Electric Company, Schenectady, N. Y.): In the technical literature, there have been few instances in which a system relaying problem has been treated in its entirety, from the complete determination of the problems to ultimate

solutions. For this reason, Mr. Kinghorn's paper, together with the Parks-Brownlee and Marter papers,[1] should prove valuable to other operating engineers.

It is interesting to note that Mr. Kinghorn and the others all chose some form of pilot relaying for the "typical" system studied. Though there can be little or no criticism of the conclusions reached, it should be noted that many systems, or portions of systems, do not yet require pilot relaying. In many instances, distance relaying, with its high-speed tripping for all faults except those near the remote line terminal, is quite adequate. Such relaying is particularly advantageous in that carrier relaying can be added easily when required.

Mr. Kinghorn rightly cautions that the second time zone of distance relays should incorporate sufficient time delay to be selective with any time delay transformer or bus differential relays. However, it is not presumed that Mr. Kinghorn is advocating the use of slow-speed bus or transformer relays since it is axiomatic that if high-speed line relaying is required, there is equal necessity for high-speed bus and transformer relays.

O. Ramsaur (Pennsylvania Power and Light Company, Allentown, Pa.): The example set by the author in putting down the requirements for the relaying on each line and comparing them with the accomplishments of the various types of relaying is one that relay engineers who are not already doing so will do well to follow. All too often it has been found that the obvious solution to a relay problem is not necessarily the best solution. With particular regard to carrier current relaying, it is evident in many cases that no other type will achieve the desired end; but once in a while it may be found that the slight additional advantage of carrier current relaying over conventional relaying is not worth the considerably greater cost and complexity.

One example pointing up this condition is a very recent case of a 132-kv tie line now being built, tying together two points in a 66-kv network. Because neither ultra high-speed tripping nor ultra high-speed reclosing is required, the line is to be tapped near the center by a 10,000-kva autotransformer, tying into the same 66-kv network, creating a 3-point line with feed-in at all three points and the condition that current flows out of the 132-kv line at the autotransformer for faults near the end of the 132-kv line. Careful analysis disclosed that to achieve instantaneous clearing of faults with carrier current relays would require remote trip and other complications that probably could never be worth either their cost or the hazard of faulty operation; and that the clearing times for a system of "zoned" instantaneous and definite time overcurrent relays we have developed for such cases is the same as that obtained by ordinary carrier current relays over almost the entire line and is fast enough for the remainder of the line. The use of conventional relays will save many thousands of dollars in first cost and will greatly reduce the hazard of incorrect operation, as they are simple, straightforward, and reliable. While this case is unusual, it does point up the injudiciousness of jumping to conclusions.

It appears that the use of the carrier current directional relays for backup purposes is contrary to the stated aim of providing back-up relays separate from those employed for carrier current. Since this is a moot question among relay engineers, it would be interesting to know why it is considered necessary to have completely separate backup relays as a matter of principle. If one would not provide separate phase backup for a straight 3-zone distance relay scheme without carrier control, it seems unnecessary to provide it with carrier current control. All the carrier current control does is by-pass the second zone timer; and shut-down of carrier removes only that feature, leaving the complete 3-zone relaying in service. Of course, backup ground relaying is required in most cases for the obvious reason that two different settings are necessary.

Also, it would be interesting to know what provision is made for out-of-step conditions.

C. E. Asbury (Commonwealth Services Inc., Jackson, Mich.): The author has no doubt found it difficult to cover this subject matter in a general way and include a variety of system conditions which are often encountered in practice. He chose to select a particular system and discuss application of relaying to certain lines in that system. Had a different line or a different system been chosen, the conclusions may have been entirely different. This should be kept well in mind when reading the paper. The author refers to this system as a typical system; however, it would perhaps be difficult to define what is required to constitute a typical system from a relaying view. Each system and line under consideration usually has certain peculiar requirements or special characteristics that set it apart from a number of other lines and systems. These individual lines and system characteristics influence the decisions of relay application. Some of the characteristics of this system which make it different from many other systems may be summarized as follows:

1. There is a heavy concentration of generation at one end of the system, busses AL and AR. If the system generation should be distributed differently or if the load was distributed differently, the relaying problem could be influenced greatly, especially as far as phase comparison carrier is concerned.

2. It appears from observing Figures 5 and 6 that there is no particular problem from the power angle swing since the impedances seen by relays do not impose any unusual conditions.

3. The lines considered on this particular application are part of a network. Had they been high-voltage radial lines to a load center (single end feed), the problem would be entirely different. Overcurrent relays with instantaneous attachments often are adequate in such applications.

4. Had the stability limits been more critical for this particular system, single pole relaying and reclosing may have been required.

One factor that influences relay application is the general philosophy and policies set forth by the particular group of engineers responsible for system operation and for protection. Some allow greater margins between relay pickup and loads or minimum short circuit current as well as impose more stringent system conditions for correct relay performance. In this particular paper the author has considered 3-phase double circuit faults and has applied relays on that basis. This is a rather severe condition; but if it can be accomplished within reasonable limits, it would perhaps be logical to do so.

However, with high-speed relaying it is rather difficult to see how a 3-phase fault could involve six conductors simultaneously (within 5 or 6 cycles) having wide spacing, such as used on 138 kv.

Considering further the margins allowed between relay pickup and minimum short circuit currents and load current, the author considered the phase comparison carrier relaying inadequate on the basis of a load of about 430 amperes and a minimum fault current of approximately 1000 amperes, a ratio of about 2.50. It should be kept in mind that as the fault location changes and moves from bus AL toward bus G, the fault current from G increases. Considering that for most high-voltage lines constructed within the past few years a performance of one or two faults per year on a line of this length (40 to 50 miles) may be expected and that experience shows that 75 or 80 per cent of these faults will be line to ground with a high percentage of the remaining 20 or 25 per cent of faults being phase to phase, it appears that a 3-phase fault may occur on an average perhaps once every six or eight years. The probability of such a 3-phase fault being in the critical section of the line, possibly 20 per cent of line near bus AL, is possibly still 5/1. Should a 3-phase fault occur near bus AL with phase comparison relaying being applied, there would be a good chance that it would clear by both ends of the line tripping simultaneously. However, if it did not, high-speed sequential tripping would occur, possibly locking the line out, which would probably be less severe on the system than the 3 phase double line fault considered.

Since the calculated risk is not very great for the application being considered, other factors such as economics might influence the decision as to the type of carrier relaying to be applied.

If the application was on an existing system where adequate backup relays existed which could not be used as part of a directional comparison carrier arrangement, an appreciable savings may be realized. Such savings would pay for an appreciable part of the phase comparison carrier arrangement.

The area described shows transmission lines supplying a total of 300 megavolt-ampere load. Mention is made in the paper of the loss of one line causing greater system losses.

Since I^2R and I^2X line losses are not normally considered in relay applications, it would be helpful if the author would clarify this problem. Apparently, this refers to persistent faults on a line which would take it out of service for an extended period of time. Is it expected that this might be caused by line burn downs caused by slow relaying? It is hardly likely that burn

downs would occur on a system such as this capable of carrying 600 to 700 amperes load current per line with fault currents in the order of 2,000 amperes for second zone tripping as mentioned in the paper, if the protection was provided by step-distance phase relays supplemented with directional ground relays and directional instantaneous ground relays at each line terminal.

The author's example emphasizes one limitation in the application of phase comparison type of carrier relaying. This limitation concerns the ratio of minimum fault current to maximum load current. It is important that the relays pick up for minimum fault conditions even when considering the fault current division from either end of the line under normal closed conditions. If complete protection for 3-phase faults is to be provided throughout the line section and if margins of about 1.5 times load current are allowed for carrier starting and minimum fault currents are to be at least 1.5 times fault detector (2) pickup, then a minimum ratio of about three is required between minimum fault current and maximum load current for the application of phase comparison carrier.

When considering backup relays, the author makes a comparison between overcurrent relays and phase comparison carrier. While there is some similarity between them there are two distinct differences in such a comparison, (1) overcurrent phase relays are susceptible to system swings, while phase comparison relays are immune to system swings, and (2) overcurrent backup relays will trip the circuit breakers when they pick up on overload. Phase comparison carrier will not produce tripping under severe load conditions, but will merely start carrier.

In this particular paper the author makes no mention of considering the application of step-distance ground relays. It would be interesting if some mention could be made of whether such relays were considered and what the conclusions were.

Mention is made of using balanced current phase and ground protection on the parallel lines. One problem that must not be overlooked in making such applications, especially for balanced current ground relays, is that of mutual coupling, which may exist between the parallel circuits and other circuits carrying ground current. This mutual coupling may disturb considerably the distribution of ground current and cause incorrect balanced current ground relay operations. Another point that must be considered rather thoroughly before applying balanced current protection, especially of the high-speed type, is the effect of current transformer residual magnetism.[1]

REFERENCE

1. THE EFFECT OF CURRENT-TRANSFORMER RESIDUAL MAGNETISM ON BALANCED-CURRENT OR DIFFERENTIAL RELAYS, H. T. Seeley. *Electrical Engineering* (*AIEE Transactions*), volume 62, April 1943, pages 164–69.

J. H. Kinghorn: In employing a specific system protection problem as a means of presenting the entire field of available tools, the final result must of necessity discard some of them for reasons which are based on judgment and experience rather than on any rigorous mathematical analysis. There is danger that the conclusions may be accepted as the only right kind in other cases where actually system requirements are less severe and a less expensive installation will give satisfactory results. It is very gratifying that the discussions have helped to bring out this point.

Mr. McConnell and Mr. Ramsauer are correct in pointing out that many systems do not yet require pilot relaying. It might even be added that there are a good many lines where simple time delay combined with instantaneous overcurrent is still giving good results. The progression from this to distance relaying and finally to pilot relaying is one which is usually dictated by increasing importance of the line because of heavier loading. Mr. Ramsauer's 3-terminal line is the well-known relay engineer's nightmare, the protection for which is sometimes difficult with distance relays, often requires special treatment with carrier current relaying, and becomes doubly difficult when the more rigid requirements of high-speed reclosing are added. Complications in relay schemes should be avoided wherever possible but they must be accepted in those cases where their use will provide definite improvement in system performance.

The extent to which backup protection should be independent of primary carrier protection is, like the choice of carrier itself, not always subject to rigorous analysis. Choice is often influenced by the engineer's experience and can lie anywhere between the one extreme of complete separation including separate current transformers, and the other of eliminating all duplicate elements and simply superposing the carrier function on the backup relaying. The modern trend appears to be in the latter direction. It was the intention to present the general problem including a possible middle ground compromise on common use of the directional relay without drawing conclusions as to how far backup duplication should go.

Out-of-step protection was not discussed because it does not present a problem in the system studied, as shown by the transient stability study. It would appear that under such circumstances its additional complications and compromises should not be employed.

Mr. Asbury rightly points out that different system requirements or a different setup could have produced different conclusions. However, as to the possibility of finding a solution to a stability problem through single-pole relaying and reclosing it should be pointed out that this requires very careful analysis, keeping in mind that single-pole reclosing usually requires relatively long reclosing time to permit fault arc deionization and that this can be disadvantageous when three pole operations are involved.

Three-phase double-circuit faults were considered only in determining system transient performance but not in determining relay applicability. Since stable operation was obtained under this severe condition there was no need for further study of other more probable but less severe faults. The relay application was based on a 3-phase fault on one line with the parallel line in service, which is the condition giving minimum current through the relays and is therefore the condition where simultaneous tripping at both ends is hardest to obtain.

In cases where phase comparison carrier relaying can show an appreciable saving in cost over directional comparison after taking backup relaying into account, the risk of an occasional high-speed reclosing failure and the small sacrifice in tripping speed may be justified. It is conceivable that in some cases a single such failure would result in expenses in excess of the amount saved and it is considerations of this sort which must determine the choice.

It is not expected that fault current in the order of 2,000 amperes would burn down a conductor even if it existed for the duration of the second zone timing. The total damage to the conductor would be caused by the combination of this current plus the total short-circuit current of 6,600 amperes which would exist until the near circuit breaker tripped. If we measure conductor damage by i^2t, we might estimate that the second zone timing increases the total damage by 50 per cent. The author does not know of any data available for determining conductor or insulator damage due to arcing which could lead to the selection of a maximum permissible arcing time, but accumulated experience with a considerable number of 132-kv transmission lines, both before and after adding carrier relaying, has shown that its addition almost completely eliminates conductor and insulator damage from this cause. Damage insufficient to produce immediate total failure of either insulator or conductor is usually considered a potential source of trouble and repairs are therefore made at the earliest opportunity. For this reason it is felt that every reasonable effort should be made to keep tripping time to a minimum.

Step-distance ground relays are a rather complicated and expensive type of relaying. They can offer the same advantage of reduced end zone time in some cases as is obtained by phase distance relays. In this case with the system solidly grounded at each station (this was not stated in the paper) instantaneous overcurrent relays give the same results as the first zone of the step-distance relay for 90 per cent of the line and for the remaining 10 per cent will trip sequentially after the remote oil circuit breaker has opened.

Transmission-Line Protection of Short Lines of the Metropolitan Area of a Typical System

W. E. MARTER
ASSOCIATE AIEE

AS A result of a study made by a Working Group of the AIEE, two companion papers[1,2] have been prepared on transmission-line protection. The papers are based on a study of a typical transmission system which is shown in Figure 1. A reactance diagram of the system is shown in Figure 2. The study was divided into three parts covering the short lines interconnecting the metropolitan area of the system, the medium length lines tying to nearby sources or interconnecting with other systems, and the long lines connecting to remote sources or systems.

This paper deals with protection which might be applied to the short lines connecting the generation and switching stations in the metropolitan area. These are the lines between station busses *B*, *C*, *E*, *F*, and *G* on Figure 1. These lines consist of three 138-kv lines of 9, 13, and 15 miles, and six 69-kv circuits consisting of three parallel circuits of seven miles each, two parallel circuits of nine miles each, and one circuit of 23 miles.

These circuits form a metropolitan network with a load of 395 megawatts and local generation of 140 megawatts. The remainder of the load in this area must be supplied from other sources which are comparatively remote from the load. The distribution of generation on the system and the fact that various sources might be shut down during light load periods indicated that difficulty would be encountered if an attempt was made to relay the short lines of the system on a time selection basis. Since the metropolitan network of the system forms the tie between various remote sources, it was felt that protection should be installed which would not be affected by through-fault or swing currents and would clear the faults as rapidly as possible. The rapid clearing requirement suggests the use of either carrier-current protection or, with the short lines involved, pilot-wire protection.

Comparison of Pilot Wire and Carrier-Current Protection

A choice between pilot-wire protection and carrier-current protection from the standpoint of speed of operation is difficult to make, as the operating time of either type is approximately one cycle.

With regard to the reliability of pilot-wire circuits, a few quotations from a report prepared by an AIEE Relay Subcommittee in 1942[3] indicates the excellent reliability of pilot-wire circuits. The introduction states: "This report is based on replies of 32 companies covering 436 circuits used for protective relaying. The information thus obtained covers 1,351 route miles of pilot-wire circuit and a period of 5,570 circuit years."

The summary, item 5, says: "The service continuity reported based on 5,570 circuit years indicates an average out-of-service time of less than 0.0335 per cent. It appears that the leased circuits have more frequent interruptions, but of shorter duration than the privately-owned circuits." An analysis of the figures in this report indicates 1.32 interruptions per circuit year with an average of 2.58 hours each for leased circuits, while the privately-owned circuits have 0.575 outages per year with an outage time of 5.08 hours per outage. The out-of-service time includes "planned interruptions" or "circuit rearrangements".

A similar report on performance of carrier channels would be of interest for comparative purposes, but no such summary is available as far as is known. It is expected that comparable information will be available.

The cost of pilot-wire protection cannot be fixed easily since the cost per terminal varies with the cost of the pilot-wire channel, assuming that one-half the cost of the pilot wire is charged to each terminal. If the cost of the terminal equipment for pilot wire is considered, the difference between that cost and the cost of a carrier-current terminal determines the maximum amount which can be spent for a pilot-wire channel.

The installed cost of a single-terminal carrier-current protection varies on the average from $6,500 to $7,500. This cost is broken down into approximately $4,500 for equipment and $2,000 to $3,000 installation costs. These are conservative figures, and in some cases, estimates as high as $15,000 per terminal have been made.

The installed cost of a single terminal equipment for pilot-wire protection is approximately $2,500 to $3,500, of which $1,200 is the approximate cost of equipment, including continuous supervision and neutralizing transformers. This allows an over-all cost of pilot-wire channel of approximately $8,000 at which figure the two schemes of protection are economically equal. If a pilot-wire channel costs more than $8,000, it is more economical to use carrier protection, and if it costs less than $8,000, it is more economical to use pilot-wire protection.

With either carrier-current protection or pilot-wire protection, it is sometimes

Paper 50-69, recommended by the AIEE Relay Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30-February 3, 1950. Manuscript submitted October 20, 1949; made available for printing December 2, 1949.

W. E. MARTER is with the Duquesne Light Company, Pittsburgh, Pa.

Figure 1. Typical transmission system showing generation, load, and line lengths

Figure 2. Positive sequence impedance diagram of a typical transmission system

necessary to remove the carrier transmitter or pilot-wire circuit from service for maintenance. Since this removal of equipment from service generally makes the relay protection inoperative, it is necessary to provide additional relay protection on the line if it is desired to keep the line in service. This additional protection provides primary protection for the line when the carrier or pilot-wire equipment is out of service, and frequently can be made to serve as back-up protection when pilot wire or carrier is in service.

Pilot-Wire Circuits

Pilot-wire circuits either may be leased from the local telephone company or owned by the power company. In some cases, power companies own telephone or other circuits which can be used for pilot-wire protection. It may be necessary to build pilot-wire circuits.

Leased Circuits

Conductors leased from telephone companies average $40 to $50 per year per loop mile of pilot-wire circuit, excluding taxes. If the $50 rental is capitalized at 12 per cent, the investment represented is $417 which would permit leasing a pilot-wire circuit 8,000/417 = 19 miles long. If an 18 per cent capitalization figure is used, the length of pilot-wire circuit which would be justified economically is increased by 50 per cent, so that the economically justified length of pilot-wire on a lease basis depends on the percentage on which the rental charge is capitalized.

Privately-Owned Circuits

If pilot-wire channels are to be built and the relay manufacturers' preference for lead-covered cable circuit is followed, the length of pilot-wire circuit is quite limited because of cost. There are in successful use several pilot-wire channels which are not in cable, which should be considered. Pilot-wire channels consisting of insulated copperweld wire closely spaced and mounted on distribution poles have been in operation for some time. In addition to low cost, this type of channel has two advantages over a telephone cable type of circuit. The resistance and capacitance of such a circuit are low and the insulation level is high.

Conductors used for such an installation are mounted on a single grooved spool and have a spacing of less than two inches. The conductors are number 10 copperweld-copper, 40 per cent conductivity with 3/64-inch performance-grade rubber insulation, American Society for Testing Materials designation *D-27*, containing 30 to 33 per cent crude rubber, and two asphalted braids slicked. Breakdown voltage of such insulation is 300 volts per mil, or slightly under 15,000 volts. Such a conductor will withstand a direct contact with a 4-kv or 6.9-kv distribution circuit without damage or any effect on the pilot-wire protection. Loop resistance is 13.5 ohms per mile of circuit. The cost of such a circuit is 4.5 cents per foot per conductor on existing poles, or slightly over $475 per loop mile. This figure is somewhat above the $50 rental figure capitalized at 12 per cent.

The use of "spiral-four" cable for pilot-wire circuits has been quite successful. This cable has four rubber-covered conductors enclosed in a foil shield and woven steel wires all enclosed in a rubber jacket. Since the war, this material has appeared on the market as war surplus material at a very reasonable cost.

Another expedient for reducing the cost of pilot-wire installations would be to use a phantom simplex circuit where several pilot wires follow the same route. No information on the use of such a scheme has appeared in any articles which have come to the attention of this author, but it seems that such a connection might have sufficient merit to be investigated, since circuits of this type have been used successfully by telephone companies for many years.

The major objection to such a scheme is that an outage on one pilot-wire pair will remove the pilot-wire protection from two lines, but usually pilot-wire outages are rare, and if adequate backup protection is provided, the double pilot-wire protection outage is not too objectionable. The simplex scheme will reduce the pilot-wire resistance, but where the simplex circuit is in, cable may raise the capacity of the pair to an objectionable value.

Backup Protection

With pilot-wire protection or any other type of protection which will not recognize a fault in the adjacent section, it is necessary to install some additional protection on the system, since a failure of the pilot-wire type of protection to clear a fault in its protected zone has no effect on the protection of this type on the remainder of the system, and therefore, a fault could remain uncleared. An uncleared fault on a system can result in serious and expensive damage to conductors and windings of equipment feeding the fault and may cause additional failures resulting in a complete system shutdown. Several cases of this type have occurred in various parts of the United States, and there is a definite justification

for expenditures for this type of additional protection on an insurance basis alone.

The additional protection is usually referred to as back-up protection and may consist of a simple overcurrent protection with or without directional features set high in time and current, or a more complicated scheme which provides a protection having operating characteristics similar to the primary protective scheme.

The two primary causes of a failure of a fault to be cleared are the mechanical failure of the circuit breaker to operate after having received the proper tripping impulse, or the failure of the protective relay system to deliver the tripping impulse.

Mechanical failure of circuit breakers to trip may be caused by a failure of any one of the many mechanical parts of a circuit breaker, such as bearing failures in any one of the many pin bearings, broken or bent trip plungers, or broken or distorted castings or other parts of the mechanism. Collection of moisture in circuit-breaker mechanism housings may freeze during low temperatures and prevent the operation of the circuit breaker.

Failure of the circuit breaker to receive a trip impulse may be caused by a failure of the instrument transformers feeding the relays, or may be in the wiring between the instrument transformers and relays. The failure may be due to open- or short-circuited windings in the coils of the relay or some foreign matter blocking the operation of the relay or to defective relay contacts. Failure may be due to failure of the tripping source or to any of the numerous contacts, coils, or wiring that comprise the trip circuit.

In order to furnish a complete backup for any or all of these failures, it is necessary to have an independent set of relays operating from separate instrument transformers and having a separate trip source tripping a separate circuit breaker or group of circuit breakers. Backup protection seldom, if ever, goes to the extent which has been described, but the condition is closely approached. The application of backup protection is influenced on any given system by past experience on the system and experiences which have been reported on other systems. Applications are made to cover failures which have had serious results in the past, or from on analysis of the system which shows that serious results could occur from a failure to clear a fault.

On any high-voltage system, the equipment which has the highest failure rate is the transmission line. Therefore, the line circuit breakers have a greater chance of failing to operate properly on a fault than any other circuit breakers on the system. It would seem then that one of the most necessary backup installations is on the line protection. It might be argued that a bus fault is more serious than a line fault, but from the standpoint of system disturbance and short-circuit current the results are the same, since the determination of whether a fault is a line fault or a bus fault is made depending on which side of a line circuit breaker the fault is located. From this discussion, it should not be concluded that bus backup, transformer backup, or generator backup is unimportant, since oil fires resulting from transformer failures and iron damage due to prolonged faults in generators can have serious effects on a system.

Protection Recommended for the Short Line

From the comparison of costs of carrier-current protection and pilot-wire protection, it can be seen that with 18 terminals involved and with a cost differential $4,000 per terminal installed, the two schemes would be economically equal if the pilot-wire circuit cost was $72,000. Since pilot-wire circuits could be built for the 99 miles of line involved for approximately $47,000, the saving in favor of pilot-wire circuit is $25,000.

An additional advantage of pilot-wire over carrier protection is the simplicity of the pilot-wire circuits and connections.

Pilot-wire protection therefore is chosen for the primary protection of these lines and provides instantaneous clearing of both phase and ground faults for the entire line.

The following items should be considered and, where necessary, included in the pilot-wire protection:

1. Rise in station ground potential and induction should be studied to determine whether neutralizing transformers are required.

2. Consideration should be given to the installation of continuous supervision on the pilot-wire circuit for the purpose of cutting out the pilot-wire protection when the pilot-wire circuit becomes defective and for the purpose of automatically switching the backup protection where simple backup is used; there also may be some question of the back-up operating unnecessarily under certain system conditions.

3. Use of instantaneous phase and ground overcurrent relays with their trip contacts in series with the pilot-wire relay trip contact should be considered. These relays have been found to be very successful in preventing unnecessary operation of the pilot-wire relays due to foreign voltage on the pilot-wire circuits from such causes as accidental application of telephone test voltages, contacts with other pairs in the same telephone cable, contacts with power circuits, and induction from circuits at voltages below the voltage of the protected line section.

4. The pilot-wire circuits should be carefully scrutinized, particularly the long circuits, to determine that the relay manufacturers' limitations with respect to resistance and capacitance have not been exceeded.

5. Pilot-wire circuits leased from telephone companies may contain loading coils, and the effect of the loading coils on the proper operation of the pilot-wire protection should be considered.

The backup protection proposed for the lines being discussed is step-distance protection with product-type ground protection. A consideration of directional overcurrent protection indicates that some difficulty might be encountered in obtaining proper time selection, since the location of power sources could vary widely with different generating sources shut down for maintenance purposes or during light load conditions on the systems.

The backup relays should be connected to auxiliary current transformers connected in the secondaries of the bushing current transformers on the line side of the circuit breaker. These current transformers normally feed bus differential, and the current transformers on the bus side of the line circuit breakers are used for the primary line protection. With this connection, the operation of the bus differential must be checked to see that it has not been adversely affected by the additional burden.

The backup relays should trip the line circuit breaker and at the same time energize a time-delay relay. The time-delay relay is set with sufficient time delay to allow the line circuit breaker to clear the fault. If the fault is not cleared, the contacts of the time-delay relay should be connected to an auxiliary relay which will clear the bus section to which the defective line is connected. The primary line protection should also operate the same time-delay relay. One time-delay relay per bus section is required for this back-up scheme.

The backup protection described provides independent relays fed from independent current transformers and provides backup for a mechanically sticking circuit breaker. It is assumed with this type of backup that failure of two pieces of equipment will not occur at the same time. As an example, if pilot-wire protection is defective, it is assumed that the current and potential transformers feeding the backup protection will not be defective at the same time.

In conclusion, it might be pointed out that on short lines requiring protection in the instantaneous classification, pilot-wire protection can be justified economically, and provides both phase and ground protection.

The backup protection chosen provides phase protection which, while not the equivalent of pilot-wire protection, provides instantaneous tripping for one circuit breaker of the line on all faults and instantaneous tripping of both ends of the line for faults in the middle 75- to 80-per cent of the line. The ground protection will require selective timing, the selection being determined from a ground fault study of the system.

With the back-up timer connected, as indicated, all possible line tripping failures are covered except a failure of the control battery.

Discussion

C. A. Mathews (General Electric Company, Philadelphia, Pa.): The open-wire pilot channels described and recommended in this paper are attractive because their loop resistance is very much less than that of the ordinary telephone cable. However, open wires are more subject to induced voltage between pilot wires than are the twisted and shielded pairs, and individual applications require checking to insure that the 15-volt maximum under fault conditions is not exceeded. Frequent transpositions of the pilot channel might be necessary to reduce this voltage difference.

The spiral-four cable referred to should be as effective as the recommended twisted pairs in reducing the voltage difference between wires due to induction. The cable shield should be grounded at points distant from the terminal stations for lightning protection.

The simplex-phantom circuit can be used, with certain precautions, for those applications where three channels are required between any two given points and where the power company is providing its own channel. Both side circuits should be spiralled in the same cable to avoid voltage difference due to induction on the phantom loop. The two side circuits can be supervised separately with little difficulty.

It might be inferred from this paper that neutralizing transformers are the only means of avoiding trouble from difference in station ground potentials or longitudinally induced voltage on the pilot wires. For those cases where all other circuits in the same cable are terminated in insulating transformers, and where the pilot wires are not connected directly to the station battery or other control equipment lacking high-voltage insulation, insulating transformers alone are sufficient.

A cost comparison on individual lines of this typical system would indicate that pilot-wire equipment is less expensive on eight of the nine lines, while carrier equipment costs less on the one line of 23-mile length, yet the authors have recommended pilot-wire equipment for all lines, apparently to avoid the inconvenience of dealing with two types of relays. On actual systems where phase-comparison carrier equipments are used on the medium length lines, they can be applied to some of these so-called short lines with a saving in cost and with no inconvenience due to introducing a different type relay on the system.

The author suggests that consideration be given to the use of supervisory relays for cutting out the pilot-wire protection when the pilot channel becomes defective in order to prevent false tripping. It should be pointed out that this practice will not prevent all false tripping, because of the high speed of the pilot-wire relays. Unless the supervisory relays are faster than the pilot-wire relays, defective pilot channels may cause false tripping whenever the load current is greater than the pilot-wire relay pickup value, depending on whether the pilot wires are short- or open-circuited.

A refinement of the product-type ground protection suggested for backup would be a directional overcurrent relay with directional control of the instantaneous as well as the time unit.

L. L. Fountain (Westinghouse Electric Corporation, East Pittsburgh, Pa.): This paper gives a needed comparison between pilot-wire and carrier-current protection of transmission lines, both from the economic as well as the performance viewpoint.

The $8,000 limit set for the economical use of pilot-wire protection seems to be substantiated where just relaying is involved. In many cases, however, supervisory control, telemetering, and communication also require pilot wires that can be included in a multipair cable along with the relay pilot wires. This might alter the economic situation in many cases to where the limiting factor becomes one of electrical performance rather than cost. In other words, where supervisory control, communication, and so forth, require a pilot-wire cable, the addition of relaying will cost very little more, since it requires only a single pair out of a multipair cable.

In some cases pilot wires do not necessarily follow the transmission line right of way, but are run over a shorter route. This can be especially true in a metropolitan area. In such a case, of course, pilot-wire mileage would have to be considered and not the power transmission distance.

In several places in the paper mention is made of the loss of protection when the pilot wire is taken out of service by a planned outage. This, I believe, would depend on the type of pilot-wire relay used and whether or not the relay pickup sensitivity is below full load current. Where the scheme is of the opposing voltage, as exemplified by the Westinghouse-type *HCB* relay, the relay may be left in service as an instantaneous over-current relay, thereby still giving protection. Where the circulating current method of pilot-wire relaying is used this, of course, is not possible.

The subject of back-up protection always brings up the question of just how far to go. The extent of backup protection described in the paper in paragraph 6 of the section on Backup Protection would certainly come under the category of duplicate protection and not backup. Whereas there are many degrees of backup protection, it generally can be defined as the tripping of the same circuit breaker by other relays or other elements in the same relay. In case of a circuit breaker failure, the tripping of the next adjacent circuit breakers by means of their relays with the necessary time delay would constitute backup protection.

C. E. Asbury (Commonwealth Services Inc., Jackson, Mich.): The author has done an excellent job in preparing this paper. His approach to the problem of economics is useful and interesting and is perhaps a point too often overlooked by relay engineers. It is realized that the cost comparisons made are only typical and they will vary with individual installations depending upon local conditions. For instance, the cost of installation of carrier current is often affected appreciably by whether or not coupling capacitors may already be available on high-voltage lines as capacitor potential devices. In some installations step-distance relays may already be available for line protection which can easily be modified to control directional-comparison type of carrier.

Some of the factors which affect leasing pilot wires are: the type of circuit available, whether local loops or whether both line terminals are located in the same exchange area, whether toll circuits are involved, and the particular telephone company's tariff, which varies somewhat in different states.

When comparing the cost of carrier current versus pilot-wire relays, one must consider whether the cost of a set of distance relays should be charged to the carrier-current installation. When phase-comparison type carrier is used, backup relays are required; however, these relays do not control the carrier. When directional-comparison type of carrier is being installed on lines equipped with modern step-distance relays, the cost comparison should not include the step-distance relays.

It would be helpful if the author would indicate whether or not the $4,500 material cost for each carrier terminal includes a set of step-distance relays. If the cost of step-distance relays has been included and is subtracted from the figure of $4,500 material cost, this gives approximately $3,200 or an installed cost of about $5,000 per carrier terminal. If the 25 per cent federal tax is considered on the telephone channel, the annual rental for a pilot-wire channel would be about $62 per loop mile. If this $62 rental is capitalized at 12 per cent, the in-

vestment represented is approximately $512, which would permit leasing a pilot-wire circuit 5,000/512=approximately 10 miles long. The paper points out that the economics involved in justifying the length of pilot wires on a leased basis depends on the percentage on which the rental charge is capitalized. As pointed out in this paragraph, other factors affecting these comparisons are: the presence of existing equipment which may be utilized as part of the carrier installation, and whether or not federal taxes are considered as part of the telephone leased cost.

One other factor that often affects the application and cost of pilot-wire relaying is the ratio of emergency load current to minimum fault current. If the pilot-wire relays are set sensitive enough to trip for internal faults for minimum generating conditions, they may require fault detectors to avoid incorrect tripping during maximum load conditions should the pilot-wire channel be open for any reason. If the system is subject to considerable variation in generation, it is often desirable that the phase fault detectors be of the distance type. This situation is often aggravated further if the pilot-wire relays are required to trip for a minimum line-to-line fault when testing the line from one end. The cost of these fault-detector relays will affect the investment required for the pilot-wire installation and should be taken in consideration where such a pilot-wire application is being compared with carrier.

Another factor which often affects the application of both carrier and pilot-wire relays is protecting lines supplying tapped loads. While this problem affects both applications, any particular application may affect the two differently, depending on the location of the tapped load, the size of the load, and the size and relative impedance of the step-down transformer bank supplying the load.

W. E. Marter: The comments of Mr. Fountain and Mr. Asbury point out additional factors involved in the economic comparison of pilot-wire and carrier-current relay protection.

Mr. Fountain's comment in connection with reduction of cost of the pilot-wire circuit due to use of a single pair in a cable installed for several functions might also apply to reduce the cost of the carrier channel due to multiple functions.

In permitting pilot-wire relays of the opposing voltage type to remain in service for backup protection with the pilot wire out of service, the only problem is whether or not it is permissible to allow the line involved to trip on a through fault or not. In general, it is undesirable to lose two lines for a fault on one line if it can be avoided. Allowing pilot-wire relays to remain in service with the pilot wire out of service would result in losing all lines with the pilot wire out of service for a fault in an adjacent line section.

The definition of backup protection would seem to depend on what is being backed up, and if it is desired to back up the protection from the current transformers through the relays to the circuit breaker, duplicate protection is necessary.

In Mr. Asbury's comments he questioned what relays were included in the cost comparison of pilot wire and carrier current. In this comparison only the cost of the pilot-wire and carrier-current protection was considered and backup protection was not included.

The use of distance carrier relays for the backup protection, although it may provide satisfactory backup for a circuit-breaker tripping failure, does not provide a backup for relay or instrument transformer failure since the same instrument transformers and relays are used for both the carrier protection and the backup.

In the cost comparison, current interlock relays were included in the pilot-wire cost, but if exceptional conditions require the use of a distance-type interlock the cost would increase.

In general, it is usually possible to set the current interlock relays so that the effect of the increased pickup of the pilot-wire protection on single-end feed to a phase-to-phase fault is minimized by setting the pilot wire below maximum through load and controlling the trip current value of the pilot-wire protection by the setting of the current interlock relays. The pickup of the current interlock relays remains the same for all fault conditions. In general, on the short lines of a metropolitan transmission network the minimum fault current is enough greater than the maximum load current to obtain satisfactory protection using current interlock relays.

In Mr. Mathews' comments it is pointed out that the open-wire pilot-wire circuit described is subject to induced voltage. This is true, but in general the open-wire circuits are run on distribution poles and are not inductively coupled with the high-voltage line being protected. This fact, coupled with the recommended use of current interlock relays, means that sufficient high-voltage current must be flowing to pick up the interlock relays at the same time a fault on a distribution circuit occurs, which induces voltage on the pilot-wire circuit.

With interlock relays set above maximum load current the supervisory relays can cut out the pilot-wire protection in the event of a pilot-wire failure, without a line tripout, and will prevent an incorrect operation on through fault current to a fault on some other line on the system.

In the interest of brevity, perhaps too many details were omitted, such as a cost comparison of the individual lines suggested by Mr. Mathews. Since the merits of carrier protection were to be presented in companion papers,[1] the author felt justified in lumping the short lines in one group and discussing only the pilot-wire protection. An additional refinement in the ground backup protection would be the use of distance ground relays to match up with the phase-distance backup protection.

Sensitive Ground Protection

AN AIEE COMMITTEE REPORT

THE Project Committee has collected information on available methods for sensitive ground relaying of 3-phase distribution and transmission systems. Several reliable methods for transmission circuits and unigrounded as well as ungrounded distribution systems have been reviewed. The limitations of presently known systems for the protection of 3-phase 4-wire multigrounded systems, as well as some results of investigations concerning "arc frequency relaying" which need further experimental study, are indicated.

In the fall of 1946, a working group was appointed to study present-day sensitive ground protection of 3-phase systems and to prepare a report on this subject. It was realized that the Project Committee would not be able to find new solutions to some of the problems, but it was felt that it would be helpful to summarize present-day practices and to give an indication where developments and improvements are necessary or desirable. A number of papers which concern certain phases of sensitive ground protection have been published during the last ten years, and they are given in the list of references, which describe in detail some of the fine points not repeated in this report.

Definition of Sensitive Ground Protection

Sensitive ground protection dealt with in this report comprises relaying of ground faults, (that is, either the indication of the faulted feeder of a system, or its automatic switching off) with fault currents to ground of a magnitude in the order of about 1 per cent of the normal or full load current of the feeder.

This will mean in general that the primary fault current will be between 1 and 10 amperes.

Objectives of Sensitive Ground Protection

1. Limitation of physical damage and reduction of number of sustained faults.

2. Facilitation of joint use with communication circuits. The degree of sensitivity proposed herein greatly exceeds the requirement of positive operation at 50 to 100 amperes in five seconds or less.[1,2]

3. Disconnection of broken conductors on the ground or on grounded objects. This is important on circuits along or crossing school yards, playgrounds, highways, and so forth.

4. Co-ordination of branch fuses, relaying and reclosing cycles of substation circuit breakers. This may be accomplished by temporarily locking out the sensitive ground relays rather than by settings above the minimum blowing of branch fuses.

Ground Relaying of Transmission Circuits

Analyses of transmission system faults have indicated a mode fault resistance of about 20 ohms with less than 5 per cent of all faults exceeding a resistance of 90 ohms. This analysis was made[3] on many systems ranging from 26 kv to 220 kv. As a general rule, adequate ground relaying of transmission circuits may be obtained with the more conventional methods and equipment.

Ground Relaying of Distribution and Subtransmission Systems

With few exceptions, only distribution or subtransmission systems will be so grounded that sensitive ground protection will become necessary. The fault current to ground is comparatively small in:

A. *Delta systems* (ungrounded systems) of small or moderate mileage. The fault current is small in such systems since it is the result of the capacity-to-ground of the system. The magnitude of the fault current to ground can be estimated for single-circuit overhead-line systems from the "rule of thumb" formula

$$I \text{ amperes} = \frac{\text{miles times kilovolts (line-to-line)}}{160}$$

B. *Systems unigrounded through high impedance.*

C. *Resonant grounded systems* (as defined in Standard AIEE number 32).[4]

D. *Effectively grounded systems* (as defined in Standard AIEE number 32) having high fault resistances, in particular in some multigrounded 4-wire systems. Small fault currents result in many cases from indirect grounds without a conductor on ground, that is, grounds with high fault resistance.

In systems as described in A, B, or C unbalances of the primary loads, and even more so their effects on the secondary side, are so small that the ground relay if connected in the common return of three identical, paralleled current transformers (four current transformers in case of 4-wire circuits) will measure correctly the ground fault current of the particular feeder. Greater accuracy may be achieved economically by cable-ring transformers.[5] Another solution are 3-phase[6] current transformers.

A. Delta Systems

Very satisfactory experiences have been gained with an installation of ground relays in ungrounded, radial delta systems of 13.8-kv operating voltage. These relays are of the directional type since they must operate only in the direction to

Paper 50-70, recommended by the AIEE Committee on Relays and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted November 18, 1949; made available for printing December 2, 1949.

Prepared by the Project Committee of the AIEE Committee on Relays. Committee Personnel: Eric T. B. Gross, *Chairman*, C. J. Berghs, R. J. Cooper, T. R. Halman, F. A. Jeanne, Cort Lowerison, W. K. Sonnemann, and A. R. van C. Warrington.

the fault. The relay sensitivity is high enough to permit relay operation on ground faults of considerable contact resistance. In many cases the fault current to ground was so small that the fault on the feeder, which had been recognized by the relay, could be found only after temporary solid grounding of another phase and repeated switching in on the fault had produced sufficiently great damage to indicate the location of the fault.

B. Systems Unigrounded Through High Impedance

In order to make possible the positive indication of ground faults, extensive tests were made by the Southern California Edison Company and a relaying system developed where grounding of 3-or 4-wire systems could be limited to one station. This system was planned originally for radial systems[7] and later extended to mesh-systems by the use of carrier channels.[8] The fault current to ground is kept below approximately 4 amperes. The grounding reactance is designed to take into account the capacitive single-line-to-ground fault current of the systems, and is low enough to produce a residual fault current which is lagging (inductive). The whole grounding system is basically a greatly overcompensated resonant grounded system, with the ground relays acting under the influence of the quadrature component of the residual feeder current.

C. Resonant Grounded Systems

Sensitive directional ground relays[9] may be used in resonant grounded systems. With this type of protection, the relays operate on the in-phase component of the residual current.

The relays used in A, B, and C are very similar, the main difference being that a different component of the residual current is used in each case to produce maximum positive torque, namely the leading quadrature component of the residual current in A, the lagging quadrature component of the residual current in B, and the in-phase component of the residual current in C. To the relay terminals of the second (polarizing) coil of this directional-type relay is supplied the voltage from neutral to ground (zero sequence voltage of the system) in all three cases in the same manner, or sometimes the current in the neutral of the grounding device.

Many operators of delta and high impedance or resonant grounded systems feel that neither a circuit nor a major part of a circuit should be disconnected to remove a low-current ground fault. A sensitive relay scheme is desirable. If the ground persisted and if desired a source of ground current sufficient to blow branch fuses with low resistance faults could be connected to the system for a definite time and removed. In any event an alarm would be sent in and operating personnel dispatched to locate and correct the fault condition.

D. Effectively Grounded Systems Having High Fault Resistance

The greatest problem in 4-wire multigrounded systems[1] is that high resistance ground faults and load unbalances have similar current magnitudes so that grounds are difficult to recognize. In a small number of systems multigrounding has been eliminated and relay schemes are used quite satisfactorily[7] as described in B. In many cases, systems operate with multiground common primary and secondary neutrals where only ground relays with current settings that are considerably higher than "sensitive ground protection" prevent relay operation on load unbalances.[1] However, fault currents to ground may be too small for relay operation if, for example, they are on a dry roadway or in contact with trees, and it is this kind of fault which makes improvements and new developments desirable.

Since it is difficult to distinguish between load unbalances and high resistance grounds, in a multigrounded system, a relay scheme which uses other than 60-cycle currents may lead to a satisfactory solution of this problem. Though a successful method of securing selective ground indication has not yet been found, it should be mentioned that tests have been made with devices which utilize the fact that arcs to ground produce high frequencies which are not present, to the same extent at least, under conditions of load unbalances. Two different kinds of equipment were tested. The one consisted of a carrier frequency receiver with coupling capacitors and traps so that the arc frequencies would be recognized. With this arrangement, it was found that the equipment reacted also without grounds on the line when equal frequencies were produced by apparatus not connected to the line, as for example passing streetcars. The other kind of equipment utilized the high-frequency current supplied from the secondaries of current transformers and filters which would eliminate low frequencies. However, it was found that not only the arcs of ground faults, but also harmonics present in the ordinary load current actuated the relay. The relays used had to have broad frequency response, since different types of arcing faults did not produce the same frequencies, and tuned relays would not be satisfactory. It is evident that extensive development and study will be necessary to clarify further possibilities of "arc frequency relaying." It should be highly desirable to continue with these experiments and tests, since they may show the way to a solution.

Conclusions

1. A reasonable sensitivity in relay protection against ground faults is highly desirable to improve service through reduction of the number of sustained faults.

2. Fault resistances on transmission systems (at 26 kv and above) are such that desirable sensitivity of ground relaying usually may be obtained with conventional schemes.

3. Fault resistances of a grounded conductor may be very high on distribution systems requiring unusual equipment and methods to provide the desired sensitivity of ground relaying.

a. Ground relaying on delta systems, resonant grounded systems, and systems unigrounded through high impedance may be provided with sensitive directional product relays, giving proper attention to current characteristics. Residual voltage devices may be used in some cases.[10]

b. Grounded neutral systems, with 3-wire circuits, or 4-wire with the neutral grounded at the supply point only, may be relayed sensitively by a number of methods such as current polarized directional ground relays with means to prevent relay damage on heavy currents, cable-ring transformers, special 3-phase current transformers, and so forth.

4. Multigrounded 4-wire distribution circuits offer the most severe problem in securing sensitive ground relaying because of unavoidable unbalances in load current and residual transients when a circuit is reclosed.

5. Radical departures from conventional methods have been tried, such as devices responding to harmonics generated by arcs but no practical success with these has yet been reported. In the present state of the relaying art, it is believed that there is no practical method of securing sensitive ground relay protection for 4-wire multigrounded distribution circuits.

Discussion

L. F. Kennedy (General Electric Company, Schenectady, N. Y.): The writer believes that the Project Committee has overlooked one item which should have been included in their report. From the general tone of the report, the reader would be justified in concluding that reliable sensitive ground relaying of ungrounded or neutralizer grounded systems could be obtained easily. Reference 9 of the paper was cited as an instance where satisfactory experience was obtained.

Unfortunately, the application of relays of adequate sensitivity will not of itself assure correct operation on fault currents of the general order of 1 per cent of load. There have been other attempts to relay both ungrounded and neutralizer-grounded systems which have not been successful. These experiences, of course, have not been made the subject of papers, so no references to them are readily available.

It should be perfectly obvious that in order to be able to have any chance for correct operation the residual unbalance of the system must be materially less than the expected magnitude of fault current. After the required system symmetry has been obtained, it is further necessary to supply the relays from current transformers of sufficient accuracy. However, a little thought about current transformer accuracies will show how difficult it may be to achieve reliable results.

The best current transformers commercially available carry an American Standards Association accuracy classification of 0.3, or, in other words, are permitted a net error including effects of ratio and phase angle of the equivalent of 0.3 per cent in ratio. With such current transformers, it is possible to have an error in the relay current great enough to cause improper performance.

The problem is not one involving basic relay sensitivity, since there are available suitable relays with sensitivity of less than one per cent. What is involved, but is not mentioned in the report, is the purely practical and economic problem of obtaining sufficient over-all accuracy to do the job. Since it is difficult to achieve system symmetry and since available current transformers may not be as good as the example cited above, it seems in order to suggest that the report should have included some statement along the following lines:

"Although relays are available with adequate sensitivity to provide sensitive ground protection for fault current of the order of one per cent of load, proper relay operation can be obtained only under conditions approaching the ideal. The ideal means the elimination of both system residual unbalances and current transformer errors."

Willard S. Wilder (Wisconsin Electric Power Company, Milwaukee, Wis.): This report is of considerable interest to us. We have an extensive rural 4,800-volt distribution system; the average substation serving an area of 38 square miles.

We would favor the indication of the faulted feeder, rather than its tripout, for the reason that we place considerable reliance for continuity of service on the ability of our 4,800-volt delta rural distribution lines to operate with one phase grounded. This is particularly important in wooded areas, where it is almost impossible to stay entirely clear of trees when the wind is blowing.

It will be realized that the system covers a lot of area, and we could hardly do business in any other manner as economically. The ungrounded operation of our rural system requires service free from interruptions, and we are able to operate quite well and economically in this manner, at least more so than by grounding and using numerous circuit reclosers.

R. W. World (Bureau of Reclamation, Denver, Colo.): As stated in the committee report, transmission systems rarely require ground-fault protection of the defined sensitivity. However, there are cases where sensitive protection might be applied even though the minimum total fault current greatly exceeded 1 per cent of normal load current:

1. If a transmission line is long and grounded-neutral transformers at the terminal stations are large, ground faults near one terminal may require sensitive relays at the other terminal for simultaneous tripping.

2. If either terminal clears line faults by opening a low-voltage circuit breaker, the other terminal may have to have sensitive relaying for sequential tripping.

3. In (1) and (2), greater relay sensitivity is required if load substation transformers tapped to the line have grounded high-voltage neutrals and either the substation is not tripped off for line faults or else a low-voltage circuit breaker is tripped. Since the critical fault locations are ones of heavy total fault current, fault resistance also accentuates the problem.

These conditions cause a disproportionate distribution of ground current among the several transformer neutrals. The need for extreme sensitivity possibly might be overcome by use of relays actuated by the positive- and negative-phase-sequence components of the current instead of the zero-sequence component commonly used in ground relays, and the application of distance ground relays is being investigated. It is expected that this relaying problem will arise in the design of some of our new transmission systems where 20-cycle reclosing circuit breakers with carrier relaying will be furnished at the main terminals of long tapped lines.

J. R. Linders (Cleveland Electric Illuminating Company, Cleveland, Ohio): This is an interesting and informative project committee report on sensitive ground protection. It will be noted that all of the methods discussed in this report rely on current-sensitive relays. We have been using a voltage-sensitive system for about 15 years with good results.

On 2,300- and 4,600-volt 3-wire ungrounded-delta radial distribution we connected a grounded-wye broken-delta potential transformer to the substation bus. A voltmeter connected across the open corner of the delta reads zero except when a ground exists on one of the feeders. Each feeder is equipped with three voltage regulators. When a ground occurs, the voltmeter will give a reading, its magnitude depending on the fault resistance and regulator position. Regardless of the actual reading on the voltmeter when the voltage regulator on the faulted phase of the faulted feeder is operated the voltmeter will change. Operation of other regulators in the station will have negligible effect on the voltmeter reading.

The only problem which we have had with this method of ground-fault location has been ferro-resonance causing the primary fuses of the potential transformers to blow. We have solved this by connecting a 40- to 150-ohm resistance in parallel with the voltmeter across the open corner of the delta-connected secondaries of the potential transformers.

Lloyd F. Hunt (Southern California Edison Company, Los Angeles, Calif.): The Southern California Edison Company has been using sensitive ground protection for may years with gratifying success.

The magnitude of sensitive ground protection is from 1- to about 6-amperes minimum trip on circuits of 2.3, 4.1, 7.2, 12, and 16.5 kv. With these low settings of ground fault tripping, unnecessary isolation very rarely occurs. Tree grounds, and the like, seem to give insufficient current to trip. In most cases, repetitive unknown trippings have been solved and in every case some de-

fect in the circuit was discovered and corrected.

The improvement in current transformers by using high-grade cold rolled steel cores have allowed the use of bushing current transformers with the very sensitive type of relaying. This is another saving in the first and installation costs of sensitive ground protection.

A great number of the circuits of the voltages listed above are now equipped with sensitive ground protection and many that require the feature are being equipped each year.

Eric T. B. Gross: The interest shown in this committee report through informal and formal discussions is greatly appreciated by the Committee. This report was presented last year, at the 1949 Winter Meeting, in preliminary form as a conference paper; it was circulated at that time among all members of the Relay Committee and also among approximately 100 other relay engineers in this country. All suggestions received were duly considered by the Project Committee and are incorporated in this report, therefore, it presents the present-day picture of sensitive ground protection in all phases of the problem.

Mr. Kennedy feels that "the Committee has overlooked one item which should have been included in this report." I believe that, had Mr. Kennedy looked more carefully at the text of the report, he would not have drawn this conclusion. It is clearly stated in the last paragraph of the section on "Ground Relaying of Distribution and Subtransmission System" that three "identical" current transformers will measure correctly the ground fault current of the particular feeder, and that this is all that is necessary, has been demonstrated in numerous practical applications. Mr. Kennedy overlooked the fact that even current transformers of very poor accuracy will not produce an error current in their secondary zero-sequence path, if current transformers are used that are practically identical as to errors in ratio and phase-angle. This fact has been known for at least 25 years to relay engineers who have been using sensitive ground relaying, and some early papers that were written on this subject[1] are mentioned in the papers which are included in the references given at the end of the report. I happen to know that a few thousand sensitive ground relays have been in successful operation abroad in resonant grounded systems where Petersen coils are designed for continuous operation, and many of these relays have a sensitivity of 0.01 ampere. Therefore, it must be concluded that the few unsuccessful attempts, referred to by Mr. Kennedy, are the very unusual cases. Furthermore, there is reason to assume that remedial measures were not tried by Mr. Kennedy. Such measures are described in the literature.[2]

As for the electrostatic unbalance of the system, mentioned by Mr. Kennedy, it should be perfectly obvious from a consideration of the equivalent circuit diagram that this unbalance with respect to ground changes the fault current by but a fraction, so that its influence is negligible. If we call E_0 the neutral displacement of the system without a ground fault, and E_ϕ any of the 3-phase voltages, the expressions for the ground-fault current will be $(E_\phi + E_0)\omega C_g$ with unbalance, and $E_\phi \omega C_g$ without unbalance. In a delta system, E_0 is always a small fraction of E_ϕ, so that this kind of unbalance is not worth mentioning. The experiences with sensitive ground protection in delta systems have been very satisfactory, as reported to our Committee. In the few cases that require balancing of resonant grounded systems, however, attempts are always made to reduce unbalances through transpositions which are desirable for other reasons. In such systems, the in-phase component of the residual current is influenced by unbalances to a somewhat larger degree; however, correct relay operation can always be secured easily by appropriate auxiliary means.

Mr. Hunt has had many years experience with sensitive ground protection; he has used current transformers of customary design in the past. It is very interesting to learn that bushing transformers also are being used now for sensitive ground relaying.

I agree with Mr. World that sensitive ground protection has its place in transmission systems. The examples cited by him are very interesting, especially his reference to distance ground relaying. It appears that distance ground relaying deserves more consideration than it has had in the past.

Mr. Wilder's viewpoint is shared by many who want to have continuity of service and prefer to operate with one phase grounded until the fault can be cleared without interruption to service. Sensitive ground relaying is of great help in such cases.

Mr. Linders' discussion is a valuable addition to the report. Since it is customary to use such feeder voltage regulators, this method seems an ideal way of locating the faulted feeder.

I know that I express the feeling of all the members of this Committee in giving thanks to all those who helped improving the report by constructive criticism, and informal or formal discussion.

Clampers in Video Transmission

S. DOBA, JR.
NONMEMBER AIEE

J. W. RIEKE
ASSOCIATE AIEE

ONE of the major problems connected with the transmission of television signals is the exceptionally wide video band of frequencies involved. For the present black-and-white standards this amounts to about 4 megacycles. In the transmission of the television signal at video frequencies, that is, noncarrier transmission, the problem is further complicated because the lower limit of the frequency range extends literally to zero frequency.

It is fortunate that the d-c and other low-frequency components need not be transmitted. However, they must be reconstructed at the receiving end for a satisfactory picture. The possibility for this reconstruction exists because of the scanning and blanking process normally used in generating the television signal. The effect of these processes is illustrated in Figures 1(A) and 1(B). Figure 1(A) shows a video signal as it might be generated by a scanning process having zero retrace time. This signal has an average value which corresponds to the average brightness of the scene. Insofar as this average value will change, the signal contains low-frequency components which extend in frequency upwards from zero.

Figure 1(B) shows the same signal after the blanking process. Here it may be seen that the effect of blanking is to multiply the original signal by a blanking wave form which is unity at all times except in the blanking interval, when it is zero. This multiplication will be recognized as a modulation, where the blanking wave form, shown in Figure 1(C), plays the part of the carrier. By straightforward Fourier analysis it may be shown to consist of a d-c or average term plus the fundamental and harmonics of the line scanning frequency.

The result then of modulating the original signal with this nonsinusoidal carrier is to obtain new frequency components. These new components are the harmonics of the line scanning frequency modulated by the frequency components of the signal. In addition to these, the original components also are present as a result of the modulation of the average or d-c value of the carrier by the signal. Therefore the original low frequencies which are present in the blanked video signal are redundant, that is, they also exist as modulation products of the line frequency component and its harmonics. Hence they need not be transmitted as long as they are reconstructed (by a proper demodulation process) at the receiving end. In this case, the tips of the blanking pulses of the transmitted wave form will describe as their "envelope" those low frequencies which have been lost in transmission.

To the blanked video wave form, a synchronizing pulse is usually added. Since this is an additive process, it does not modify the discussion above.

To indicate how low frequencies are lost in transmission, consider the wave form due to a half-white half-black field with a horizontal line of demarcation as indicated in Figure 2(A). This is a video signal complete with horizontal synchronizing pulses, though for simplicity the vertical synchronizing pulses are not shown. If the average value of this signal is removed, due to lack of d-c transmission, the tips of the synchronizing pulses will extend below the zero voltage line, in a negative direction. If the average value of the signal changes, the extension of the synchronizing pulses in a negative direction also will change. This effect has been called the "zero wander."

It may be seen that any process which lines up the tips of the synchronizing pulses at the zero, or any other fixed, level reintroduces these low frequency components lost in transmission.

Moreover, it is evident that this reinsertion is nothing more than a sampling process, that is, the wave is sampled periodically and any deviation from zero is corrected. In common with all sampling processes the highest frequency component which may be regenerated by this means is limited to a frequency of one-half the sampling or line frequency. For practical reasons, the maximum frequency which may be regenerated is limited to a considerably lower value.

Low-Frequency Transmission Problems

In order to study the low-frequency transmission effects, the wave form of Figure 2(A) will be used, since it has the maximum field frequency (60-cycle) component. The analysis can be considerably clarified, however, if we separate this signal into two components as shown in Figures 2(B) and 2(C). The former of these contains the high frequency components and virtually none of the lows, while the latter contains the low-frequency components and virtually none of the highs. Since only 75 per cent of the video amplitude and 85 per cent of the time are used for picture information, the amplitude of the low-frequency signal of Figure 2(C) (in terms of a 1-volt video signal) is: $0.75 \times 0.85 = 0.64$.

By the separation of the high-and low-frequency components, the problem of investigating transmission deviations in the low-frequency region is considerably simplified. For this purpose it is sufficient to consider the wave of Figure 2(C) only, on the assumption that the wave of Figure 2(B) will be transmitted faithfully.

Consider the effect of a single low-frequency cut-off consisting of a series capacitor and shunt resistance, of time-constant T. For a value of T moderately

large compared to the field (60-cycle) frequency, the effect of applying the wave of Figure 2(C) will appear as shown in Figure 2(D), that is, the main characteristic of such distortion is to produce a slope, or tilt, in the wave form.

As the number of low-frequency cut-off circuits in the transmission system is increased, the resultant distortion remains essentially the same provided the time constant of each is increased in proportion to the number of circuits. When viewed on a picture monitor, this type of distortion results in a shading which is most noticeable in the darker portions of the picture. It is evidenced by a decrease in brightness in the region immediately following the white portion of the picture, which decrease in brightness shades to an increase in brightness in the region immediately preceding the white portion of the figure.

A change in brightness corresponding to a slope in the low-frequency wave, Figure 2(D), of 1 per cent, for example, would be produced by a single low-frequency cut-off element having a time constant of 0.4 second. In terms of the steady-state transmission characteristic, the 3-decibel loss point occurs at 0.4 cycle and the phase shift at 60 cycles amounts to 0.38 degree. For large numbers of cut-off circuits in tandem, the 60-cycle phase shift adequately describes the resulting wave form slope.

The extremely low frequencies which must be transmitted, as indicated before causes considerable difficulties particularly when coupled with the 4-megacycle band width required for the transmission of fine detail. This is a serious practical matter, since to obtain wide band widths and reasonable gain from vacuum tube interstage circuits the parasitic capacitances must be made small. To pass the low frequencies, however, requires large coupling capacitors with a resultant high parasitic capacitance.

Furthermore, under these conditions, the use of transformers as coupling elements has been impossible due to the difficulty of incorporating the extended low frequency cut-off and wide band width into one design.

One method of reducing the low-frequency range is to utilize a circuit which reduces phase shift at the field frequency. This is the well-known plate decoupling or low-frequency compensation circuit, which is shown in Figure 3. The effect of this circuit is to place a "bump" in the transmission characteristic, usually well below the field frequency. The phase shift at the field frequency is materially reduced. The net effect is that the "slope" or tilt of the low-frequency signal is eliminated. If the gain bump produced extends up to field frequency, a slight "bow" distortion may be produced.

With this artifice it is possible, at least theoretically, to reduce the size of the coupling capacitor in the interstages and compensate, by means of the plate decoupling circuits, for the distortion produced.

There are two difficulties attendant to this procedure. The first lies essentially in a balance of distortions. This may be seen most readily by considering the plate circuit as a predistorter and the grid circuit as a restorer. Obviously if the predistortion and restoration are considerable, a precise balance between the two is required to limit the net distortion to a threshold value. A further difficulty arises from the magnitude of the gain bump produced. This is serious only when a considerable number, ten or more, of coupling circuits are employed.

The effect of a high gain bump is most noticeable on switching transients such as are caused by switching from one circuit or camera to another and is seen as a low-frequency damped oscillation. For these reasons the benefits to be derived from low-frequency compensations are limited.

Regeneration of Low Frequencies

The analysis of distortion has so far neglected the distortion produced by the deletion of the d-c or average value of the video signal. For a still picture this distortion could be eliminated by a manual adjustment of the background brightness of the picture monitor.

When there is motion in the picture, however, an automatic means is required. This need is met by the so-called "d-c restorer," a schematic of which is shown in Figure 4. The operation of the d-c restorer is as follows. The diode is arranged so as to conduct on the synchronizing pulses. With the diode resistance low enough in the conducting direction, the coupling capacitor will be charged to such a value as to just reduce the diode current to zero. The voltage on the following grid at this instant will be zero, and hence the video signal will be positive for the picture time. If for any reason, such as zero wander, the synchronizing pulses tend to go more negative, the coupling capacitor is quickly charged by the diode so that the minimum signal at the grid is again zero. If on the other hand the synchronizing pulses tend to go more positive, the diode ceases to conduct. However, the shunt resistance across the diode discharges the coupling capacitor to such a value as to cause the diode to conduct again on the synchronizing pulses. Hence the line-up of synchronizing pulses is maintained. In effect, the d-c and those low frequencies lost in transmission have been regenerated by the d-c restorer.

Figure 3. A low-frequency compensation circuit

A shortcoming of the d-c restorer lies in the finite resistance of the diode in the conducting direction. As a consequence of this the blocking capacitor never becomes charged to the full peak value of the synchronizing pulses, but a part of the synchronizing pulse at the grid extends in the negative direction. The amount of this extension depends upon the wave shape of the video signal. The net effect of this is that a certain amount of residual distortion is always present.

The d-c restorer, as an element in a system designed to maintain low-frequency cut-off distortion at threshold values, has a further disadvantage. For positive operation as a low-frequency restorer, the resistance-capacitance time constant of the restorer should be small compared to that of the system which precedes it. This means that the net system low-frequency distortion after restoration will be due mainly to the restorer instead of the multitude of system cut-off elements. Hence, it should be used only for the restoration of d-c and very low frequencies.

The shortcomings of the d-c restorer are overcome in a device called a clamper. A simplified schematic is shown in Figure 5, from which it may be seen that this form of clamper is merely the d-c restorer with a pulse-operated switch replacing the diode and resistance. In this form the clamper may be defined as a pulsed d-c restorer. The pulses used are normally the synchronizing pulses.

The clamper has over the d-c restorer the advantage that a low impedance to ground is obtained whenever the clamper switch is closed, that is, during the synchronizing pulse time. Hence the coupling capacitor may be rapidly charged or discharged to maintain line-up of synchronizing pulses. During the remainder of the time, the switch is open and no leakage path to ground need be provided. Hence the clamper does not of itself cause distortion of the signal.

If we consider the clamper as a demodulator, then the demodulated wave form is that which exists across the coupling capacitor. This wave form is a staircase or stepped wave and may be called the envelope since it is the negative of the envelope of the tips of the synchronizing pulses at the clamper input. The output of the clamper is the input wave minus its envelope.

For the case of a transmitted still picture, which lacks only its d-c value, the derived envelope will be this d-c value. Hence the clamper output will contain the original signal including the d-c component.

For the case of a transmitted moving picture from which the direct current and low frequencies have been removed, the derived envelope will contain the direct current and, to a varying approximation, the low frequencies up to half-line frequency. Above half-line frequency the derived envelope is no longer even an approximation to the deleted frequencies.

Although clamping has been referred only to the synchronizing pulses, any reference or datum value of the signal may be used. These also occur at the front and back "porches" of the standard video signal. For certain uses, such as in picture monitors, back porch clamping may be advantageous inasmuch as the black level is maintained more nearly independent of signal amplitude than if synchronizing pulse clamping is employed. For most purposes, however, the attendant difficulties of generating delayed pulses necessary for back porch clamping make its use less attractive.

Operation of Clampers

The low-frequency cut-off of a video transmission system produces a distorted video signal at the output which may be thought of as the sum of the undistorted video wave form and a low-frequency distortion wave. The low-frequency wave is the negative total of all the low frequencies lost in transmission. It is intended that the process of sampling at the line frequency synchronizing or blanking times will yield substantially this low-frequency distortion wave form. The sampled distortion envelope can then be subtracted from the distorted video wave form to yield substantially undistorted video. However, sampling at finite intervals can yield a wave form which is correct only at the time of sampling. Between intervals the envelope wave yielded by sampling remains constant while the low-frequency distortion wave form which is sampled is continuously changing so that when the derived wave is subtracted from the input wave, a residual distortion remains. This is illustrated in Figures 6(A), (B), (C). Figure 6(A) is a typical low-frequency distortion wave such as might be due to a single resistance-capacitance cut-off acting upon a video wave form which contains a square wave of low frequency. Figure 6(B) shows the wave which is derived by sampling the low-frequency wave at a finite rate. Figure 6(C) shows the wave form which remains when the sampler derived wave is subtracted from the low-frequency wave.

Figure 4. The d-c restorer circuit

Figure 5. A simplified clamper circuit

The residual distortion wave form of Figure 6(C) produces a characteristic raster distortion pattern. The effects of low-frequency cut-off distortion when clamped are zero at the left side of the raster and increase toward the right so that the effects are first noticeable along the right edge of the raster. These effects are characterized by sudden changes in the background which occur whenever the low-frequency distortion wave suddenly changes slope. Such slope changes will occur wherever there are sudden vertical divisions in brightness as might be the case at the horizon in an outdoor scene. Figure 7 consists of raster photographs where the picture material is an artificially generated white square. Figure 7(A) is an undistorted case. Figure 7(B) shows the low-frequency cut-off distortion caused by a single resistance-capacitance coupling network when no clamping is employed. Figure 7(C) is the same raster after the cut-off distortion has been reduced by clamping. The time constant has been chosen small enough so that the distortion may still be seen in the clamped case. It appears as a dark streamer to the right of the square.

The peak-to-peak amplitude of the residual distortion establishes the low-frequency cut-off requirement of a system which employs a clamper. This amplitude is equal to the amount of slope in the

Figure 6 (left). The result of clamping low-frequency distortion

Figure 8 (right). Peak interference reduction by clamping

low-frequency wave form, Figure 2(D), which accumulates during the time of one scanning line. The amplitude in the nonclamper case is the slope which accumulates over one-half frame scanning time. For equal distortion amplitudes in the two cases, a possible reduction in the required low-frequency time constant due to the use of clampers is about 65 times. The lowered value of the cut-off time constant simplifies video interstage design and permits the use of transformers, with their attendant advantages, as video coupling elements.

Figure 7(A). A white rectangle with a grey background. No low-frequency cut-off distortion

Figure 7(B). The effect of a large amount of low frequency cut-off distortion

Figure 7(C). The effect of clamping applied to the signal of Figure 7(B)

The subtraction of the sampled envelope of the input wave from the input wave itself is as effective in reducing low-frequency interference as it is in reducing the distortion caused by the low-frequency cut-off of the transmission system. The low-frequency interference may be comprised of any number of low-frequency sine waves which are added to the video wave form during transmission. When this wave is sampled at a rate which is high compared to the interfering frequency, the derived envelope is similar in form to the interfering wave but progresses in the manner of a staircase. As the interfering frequency is lowered the sampled envelope becomes a better and better approximation to the input wave so that after substraction a smaller and smaller interference remains. The residual interference has a maximum value given by the maximum change of the input wave in the time of one scanning line. Where the time of one scanning line is T_0 and the interference is of the form; $\epsilon = \sin \omega t$, the remaining interference, R, is given by: $R = \sin \omega(t+T_0) - \sin \omega t$ and has a maximum value, (when $\omega t = -\omega T_0/2$), equal to $2 \sin \omega T_0/2$. This function is plotted in decibels in Figure 8(A) for values of interference frequency, (f), from 20 cycles to 15750/2 cycles. This curve represents the ratio of peak output distortion to peak input distortion achieved by ideal low-frequency clamping of this form. The suppression of 60-cycle power frequency interference by 33 decibels might alone justify the addition of a clamper in many situations.

High-frequency interference is affected by clampers in a manner altogether different than low-frequency interference. The derived envelope no longer resembles the interfering input wave but has a low recurrence frequency which is the beat between the interfering frequency and the nearest multiple of scanning line frequency. The process is illustrated in Figure 9 which shows an interference frequency nearly equal to scanning line frequency and the resulting low recurrence frequency of the derived envelope.

Reference to Figure 10 will serve to show how this generation of low beat frequencies may degrade intolerably a system which is otherwise acceptable. The signal-to-noise ratio which is required of an acceptable system falls off rapidly as the frequency of the "noise" is increased. If from a high-frequency interference having a low signal-to-noise requirement the clamper generates a beat frequency having a high signal-to-noise requirement, the effective requirement at the high interference frequency is determined by the requirement for the generated beat frequency and becomes severe at all frequencies.

When the interference is in the form of wide band random noise, the derived envelope has a random value from line to line which is unrelated to the noise during the picture time so that the envelope when added back into the video contributes an additional random interference. This interference has the appearance of streakiness in the picture. It might be well to point out that the clamper is not affected by the characteristic noise of the camera tube because this noise does not appear in the synchronizing region. Random noise added into the system beyond the blanking stage will presumably exist in the synchronizing region and will generate the streakiness in clamper output.

A possibility for reducing the amplitude of beat frequencies generated by the clamper exists in the finite duration of the synchronizing pulse during which time the envelope is derived by sampling. A process of averaging over this duration in the derivation of the envelope yields a beat frequency amplitude which is equal to the interference wave amplitude multiplied by the function, $\sin \pi f\tau / \pi f\tau$ where τ is the time duration of the synchronizing pulse and f is the frequency of interference, (see Appendix II). This function at high frequencies decreases as $1/f$.

Figure 9 (left). The low-frequency beat which is generated by the clamping of a high-frequency interference waveform

Figure 11 (right). The reduction in amplitude of generated beat frequency as a function of clamper time constant

Averaging of this kind will reduce the beat frequency amplitudes to values such that they will no longer affect the interference requirement at high frequencies. At frequencies between 2.5 kc and 100 kc the function $\sin \pi f\tau / \pi f\tau$ has not yet become effective in reducing the generated beat frequency amplitude. In this region the signal-to-noise requirement is perhaps 6 decibels worse with clampers than without. This seems to be a minimum penalty to be paid for the use of the clamper.

The averaging of the values of the interference over the time duration of the synchronizing pulses is accomplished by means of a time constant in the envelope detector circuit. A resistance-capacitance circuit has been employed thus far and modifies the generation of the envelope as follows. The envelope follows the low-frequency wander of the video wave form abruptly at the beginning of the synchronizing pulse when there is no time constant. When a time constant is employed, however, the envelope voltage cannot change suddenly, but during each synchronizing pulse approaches exponentially the changed level of the video wave form. The instantaneous envelope detector follows a high-frequency interfering wave form without attenuation during the synchronizing pulse so that at the end of the synchronizing pulse the instantaneous value of the interfering wave remains as the envelope voltage. When a time constant is employed the interference is attenuated so that the envelope voltage at the end of the synchronizing pulse is less and less determined by the interference as the frequency of the interference is increased. The amplitude of this generated envelope beat frequency versus the interference frequency is plotted in Figure 11. The derivation of the curves is developed in Appendix I.

The addition of a time constant to reduce the generation of beats from high-frequency interference reduces somewhat the efficiency with which the clamper acts to suppress low-frequency distortion and interference. The increase in low-frequency clamper output distortion as a function of the clamper time constant is shown in Figure 12, for the standard wave form having a synchronizing pulse width equal to 5 microseconds (see Appendix II). The curves of low-frequency interference reduction, Figure 8, show the same effects of clamper time constant to reduce the effectiveness of the clamper as a low-frequency interference suppressor.

Reference to these curves and the curves of beat frequency amplitudes, Figure 11, show that great reductions in beat frequency amplitude at high interference frequency are possible with only a slight decrease in the low-frequency performance of the clamper. Evaluation of these data make it possible to choose a value for this time constant of about 2.5 microseconds as being close to an optimum value. With this choice, low-frequency performance is degraded about 1.5 decibels while the beat frequency output at 1 megacycle has been reduced 22 decibels. This value of time constant has been incorporated into the clamper circuits to be described. In the frequency region from 2.5 kc to 100 kc the maximum amplitude of the generated low-frequency beats is not much reduced by the time constant of the clamper so that in this region the transmission interference requirements are about 6 decibels worse when clampers are employed.

Clamper Circuits

The usual form of clamper, which we shall designate as the series capacitor clamper, is shown in Figure 5. In this case the envelope is obtained across capacitor C by the periodic closing of the switch, S. The closed period corresponds in time to the synchronizing pulse time of the video wave form so that the capacitor is charged to the value of the video wave at this time. The charge acquired during the closed period remains unaltered during the open period, and therefore represents an envelope of the peak voltage of the video wave form during the synchronizing pulse times. The output voltage is then obtained as the difference between the input voltage and the sampled envelope.

The rapidly closing switch is achieved electrically by a pair of diodes as shown in Figure 13(A). These diodes are caused to conduct during the synchronizing pulse intervals by driving pulses of the same form as the synchronizing pulses. The diodes and pulses taken together constitute a switch between the signal point and ground because periodically they present a low impedance to ground.

Figure 13. The series capacitor clamper circuit and its electrical equivalent

A. The diodes and driving pulses
B. The pulsed diode equivalent
C. Envelope feedback to reduce diode distortion and resistance

None of the driving pulse voltage, ideally, is transmitted to the signal path because the pulses are coupled to the signal path in equal magnitude and opposite polarity and generate only a loop current in the diode circuit. The capacitors and resistors associated with the circuit provide a biasing arrangement so that the diodes will conduct at the peaks of the driving pulses and be well cut off between conducting periods. The value of bias which is developed determines the maximum value of voltage that may be transmitted in the signal path of the circuit. Higher signal voltages will cause diode conduction during normally nonconducting periods. This consideration furnishes the requirement for the required driving pulse amplitude since the bias voltage is equal to the peak amplitude of the driving pulse voltage.

The circuit impedance at the output terminal of Figure 13(A) during periods when the switch is open, is ideally the clamper capacitance itself. However, associated with the circuit at this point are possible leakage paths to ground such as the diode elements and the grid of the amplifier which utilizes the clamper output. This leakage results in a change in capacitor charge between clamping pulses and is made evident as horizontal shading in the output picture. The leakage current then argues for a large capacitor. Limiting in the other direction is the 2.5-microsecond capacitor charging time constant required and the minimum value of charging resistance which can be secured. This charging resistance is comprised of the resistance of the diodes and the resistance of the signal source. The signal source, has, therefore, been chosen to be a cathode follower and may have an impedance of 100 to 200 ohms. The effective resistance of the diodes when they are conducting is of the same order so that a total charging resistance of 200 to 300 ohms is obtained in this form of circuit. Such a value yields 0.01 microfarad as about the maximum value for the charging capacitance. With this value of capacitance a leakage resistance of 10 megohms would yield the amount of horizontal shading equivalent to a 0.1 second time constant and is considered to be a tolerable value for the shading due to a single circuit element.

The combination of diodes and driving pulses departs from an ideal switch in two ways; it has resistance as mentioned before and it is subject to unbalance. The unbalance results in placing on the clamping capacitor a charge due to the driving pulses and as these pulses vary in form through the vertical synchronizing pulse region the amount of charge coupled to the clamping capacitor will likewise vary, producing in the clamped output a distorting envelope voltage. Schematically this distortion might be represented as a voltage source in series with the switch as in Figure 13(B) where it is labeled Δ. This figure shows conditions which exist when the diodes are conducting. Ideally the output at this time should be zero but due to the diode resistance r and the voltage source Δ a residual output is present.

This residual output during the conducting period can be reduced considerably if feedback is employed in the manner shown in Figure 13(C). The residual voltage appearing at the output terminals is amplified and reversed in polarity by the amplifier labeled, $-\mu$. The amplifier output is returned through the clamper switch, S, and the diode resistance, r, back to the output terminals. Circuit equations reveal that both the diode resistance, r, and distortion, Δ, are effectively reduced by a factor, $(1+\mu)$. The factor, $(1+\mu)$, is recognized as the feedback of the circuit.

When clamping is to be accomplished during synchronizing pulse intervals the diode driving pulses preferably should be pulses of the same duration as these intervals. A suitable source of such pulses is the clamped output signal itself. The output signal is amplified by two amplifiers having amplification factors of $-\mu_1$ and $+\mu_2$. The outputs of the amplifiers are coupled to the diodes which are polarized to conduct during synchronizing pulses and remain nonconducting between synchronizing pulses.

When μ_1 and μ_2 are of equal magnitude this arrangement provides the equivalent of the switch, S, together with diode resistance, r, and distortion, Δ, shown in Figure 13(B). If μ_1 is greater than μ_2 a negative feedback circuit exists. The magnitude of the net feedback $(1+\mu)$ is equal to $1+(\mu_1-\mu_2)/2$, and is useful in reducing the effects of the diode distortion and resistance as in Figure 13(C).

When the diode driving pulses are derived from the video wave form there is a requirement that the maximum envelope distortion from one line to the next must not exceed the amplitude of the synchronizing pulse since amplitude selection is the basis of pulse extraction. Envelopes greater in amplitude than synchronizing pulse result in video information being present at the pulse clipping amplitude level. Low-frequency interference or distortion having an amplitude greater than the synchronizing pulse amplitude is tolerable because it is progressively removed from line to line by the clamper. This restriction affects primarily the response of the clamper to sudden transients such as impulse noise or contact noise.

There is another approach to the clamping problem which is suggested by feedback amplifier techniques. Figure 14 illustrates the method. The switch and capacitor combination are rearranged so that its useful output is the envelope voltage rather than the difference between signal and envelope as in the case of the series capacitor clamper. This envelope detector is a β circuit element in a feedback circuit, arranged to reduce the overall forward gain to distortion and interference voltages without affecting gain to a video wave form which is free of such voltage. The result of such an arrangement is an improvement of signal-to-noise ratio by the amount of loop gain employed.

Figure 14. The envelope detector as a circuit element in a feedback clamper circuit

Figure 15. Series capacitor clamper (W.E. 1-B clamper-amplifier)

The feedback loop includes an amplifier connected from the output point to the envelope detector. This amplier contains no video distorting elements and provides all the loop gain required. The envelope detector extracts from the amplified video any envelope voltage which may be present. Its output will be of the form of the wave shown in Figure 6(B). This output is coupled to the video input circuit through a coupling amplifier which is usually necessary as an impedance transformer.

In the forward path of the feedback loop there may be transmission elements of a wide variety of forms. The envelope distortion which might normally be introduced by these elements is reduced by the feedback in the same way as input distortion. These elements might include nonvideo components such as amplitude-modulation or frequency-modulation components delivering an output carrier wave rather than a video wave. In such a case complementary elements would be included in the feedback path to restore the signal to a video wave form at the envelope detector input terminals. The carrier counterpart of the video distortion would then be suppressed.

The effective clamping time constant for the feedback connection is the time constant of the envelope detector divided by the feedback factor, $1+\mu$, (see Appendix III). In order, therefore, to secure an effective time constant of 2.5 microseconds, the envelope detector time constant is increased by increasing the capacitance or driving resistance or both. In terms of the $\mu\beta$ frequency characteristic the effective 2.5-microsecond time constant means that $\mu\beta$ is reduced to unity at a frequency of about 64 kc. The phase shift of $\mu\beta$ at this frequency will be 90 degrees plus whatever phase shift is contributed by the high-frequency cut-off of the remaining circuits. Since these circuits would normally extend to about four megacycles they contribute phase shift at 64 kc of the order of one degree per circuit and high-frequency feedback stability should be easily obtained.

Stability against oscillation at low frequencies will usually present greater difficulties. It is important that $\mu\beta$ be maintained at a large value beyond the lowest distortion or interference frequency which must be suppressed. Cutting off the loop gain in an orderly manner in the region below a few cycles per second is in most cases impracticable. An alternative to cutting off $\mu\beta$ at the low end is that of maintaining the feedback loop gain to zero frequency. This pro-

Figure 16. A transmission line bridging clamper of the feedback type

cedure avoids the cut-off problem and results in the additional advantage that those elements within the feedback circuit are d-c stabilized at the clamping pulse intervals. In this manner the value of carrier radiated by a television transmitter could be maintained at a constant value at synchronizing pulse times by including the transmitter as one of the forward path elements of such a clamper feedback loop.

Two examples of clampers will now be described in detail. The first is a series capacitor clamper-amplifier which has application as a video line terminating amplifier. The second clamper is of the feedback type and is a device which may be bridged across a video line to suppress video distortion and interference and which, incidentally, serves to measure the peak-to-peak video voltage existing at this point.

Series Capacitor Clamper Circuit

The Western Electric Company *1B* clamper-amplifier is shown schematically in Figure 15. It fulfills the 2-fold function of reducing low-frequency distortion and providing a maximum of 18 decibels gain. The amplifier proper is comprised of an input amplifier providing about 12 decibels gain, and an output amplifier with 6 decibels gain. The clamping capacitor (*C4*) is the coupling element between the two. A gain control consisting of a stepped potentiometer having nine two decibel steps and a 1-decibel attenuator is provided at the input to control the over-all gain.

The input amplifier utilizes a *2C51* double triode vacuum tube in a direct-coupled circuit. The output triode is used as a cathode follower and provides a low-impedance (about 250 ohms) facing the clamping capacitor. The coupling impedance between the two triodes consists of a 2,000-ohm resistance and inductance *L1* comprising the high-frequency impedance. An additional 18,000 ohm resistance (*R18*) shunted by a 0.5-microfarad capacitor (*C3*) provide a gain increase at low frequencies. This compensates to some extent for whatever low-frequency distortion may be introduced ahead of the clamper and in general permits a greater amount to be tolerated. A variable resistance (*R17*) is provided so that the amount of this low-frequency gain increase may be reduced if necessary by introducing a loss in the input grid circuit.

Provision is made by means of switch S_1 for disabling both these functions as well as turning the clamper off when it is desired to study the distortion existing ahead of the clamper. This is accomplished by shunting *C3* with an additional 125-microfarad capacitor (*C13*) and by raising *R17* to its maximum value of 1 megohm. The clamper is disabled by turning off the heaters of the clamper diodes (*V8*).

The output amplifier is a 3-stage cathode feedback amplifier utilizing two *6AK5* vacuum tubes, *V2* and *V3*, for the gain stages and two *2C51* tubes, *V4* and *V5*, in parallel for the output stage. These output tubes are operated at zero bias with d-c insertion on the grids to provide the required maximum output of 2.5 volts.

The output is normally obtained from the plates of the *2C51* tubes to provide an unbalanced signal on a 75-ohm line, but also by utilizing the voltage across the cathode circuit, a balanced signal with a 110-ohm impedance may be provided. A switch S_2 is utilized to change readily from one to the other. A 5-decibel pad in the balanced output path is used to maintain the output signal at the same value (normally two volts) for either condition.

The feedback used in the output amplifier is of a type calculated to achieve the greatest stability of forward transmission characteristic of a video amplifier. The maximum feedback is about 48 decibels and falls off at the rate of 6 decibels per octave. The value is about 15 decibels at 4 megacycles, and results in a high degree of stability. In the present amplifier the external gain change, for an internal gain change of about 6 decibels, is less than 0.1 decibel up to 4 megacycles. The over-all frequency response may be made flat to about 8 megacycles by proper adjustment of *L1*.

The input to the clamper drive amplifier is obtained from the resistance *R24* in the cathode of *V2*. Since this point is beyond the clamping capacitor, the video signals here are clamped and

suitable for driving the clamper diodes. Cathode voltage rather than the grid voltage of *V2* is used because of the lower impedance level of the former. This reduces the shunting effect of the input impedance of the clamper-drive amplifier.

Vacuum tubes *V6* and *V7* comprise the clamper-drive amplifier with the former serving as an amplifier-phase inverter and the latter as two cathode followers to drive the diodes from a low impedance point. In order to obtain a net negative feedback around the clamper drive circuit, the drives for the two halves of the clamper diodes (*V8*) are made unequal. In the present instance these values of driving pulse gain are proportioned to yield a net feedback of 15 decibels.

The clamper drive voltages are coupled to the diodes through capacitors *C15* and *C16*. Because of the rectifying properties of the diodes, these become charged to almost the peak value of the synchronizing pulses, and hence the diodes are biased below cut-off for the part of the signal containing the picture information. The values of resistors *R49* and *R50* are chosen high enough to maintain this charge almost undiminished between synchronizing pulses, while their ratio is made such as to maintain zero bias with respect to ground at the grid of *V2*.

The proper operation of the clamper depends upon the signal amplitude available to bias the diodes. If this is too low, the diodes will become conductive during all or part of the picture time and hence introduce considerable distortion. With a normal signal output of 2 volts, there is about a 10- to 12-decibels margin in operating value. That is, the output signal may fall to about 0.5 volt before the clamper fails.

Shunt Feedback Clamper-Voltmeter

The clamper described next is a device which is bridged across a video transmission line. It has two functions. Firstly, it removes, by clamping, the low-frequency distortion and interference that may be present at the bridging point. Secondly, it measures the amplitude of the clamped video wave form from the tips of the synchronizing pulses to the extreme values of the wave form in the direction of highest brightness. A meter is used to indicate the peak-to-peak value of clamped video voltage existing at the bridging point. Thus, it provides the video equivalent of the program volume indicator which now is standard equipment in sound program circuits.

Repeated use of a video level indicator which functions also to clamp the signal will maintain low-frequency distortion and interference at low levels. Thus, the likelihood of intermodulation between these components and the video signal is reduced.

This clamper is an example of the feedback method of clamping described previously and illustrated in Figure 14. In this case the forward elements reduce to a pair of blocking capacitors used for d-c isolation of the clamper. The transmission line is electrically equivalent at the bridging point to a voltage source, E, appearing through a resistance equal to one-half the characteristic line impedance. The signal at the bridging point is amplified and applied to the envelope detector. The detector output which appears as a voltage across capacitor, C, is returned to the transmission line bridging point by means of a coupling amplifier which for illustration is assumed to have a voltage gain of unity working into one-half the line impedance. This feedback envelope is out of phase with the original distortion due to E and therefore reduces the net distortion existing at the bridging point. The amount remaining in the output can be made negligibly small by employing sufficient gain between the bridging point and the envelope detector.

Referring to the schematic diagram, Figure 16, the feedback loop is seen to consist of two video gain stages ahead of the envelope detector and an output coupling stage consisting of two similar circuits in parallel to inject the envelope back into the bridging point. The bridging point is isolated from the transmission line by two 3,000-microfarad capacitors to remove any direct voltage that may be present on the line and which the clamper could not tolerate. The video distortion in the output occasioned by the 3,000-microfarad capacitors is negligible.

V_1 and V_2 are together the first video gain stage and there is present negative feedback of about 6 decibels from the cathode of V_2 to the grid of V_1 for the purpose of linearizing the output. The cathode of V_2 is coupled to the input of the next video gain stage by means of a gas tube, V_3, which drops the d-c potential by 105 volts to obtain correct d-c input conditions at the second gain stage. This is the d-c coupling which was spoken of when discussing stability requirements. Every stage is so coupled that the loop gain is maintained from zero frequency to the upper frequency at which the envelope detector cuts off.

As a result of the d-c feedback and the action of the envelope detector, the instantaneous potentials within the feedback loop are stabilized at fixed values at the synchronizing pulse times regardless of signal level or picture content. This assures that the optimum operating point obtains at synchronizing pulse times and that distortion will be minimized at this part of the signal wave form.

A by-product of great usefulness is due to this d-c stabilization of the synchronizing pulse value of the wave form. This means that, if a rectifier is connected to obtain the peak value of signal departure from the d-c level with no signal applied, then the rectified voltage is a measure of the peak-to-peak video input level and a peak-to-peak meter of good characteristics results. *V17* is such a peak rectifier diode and the rectified voltage is applied to a meter by means of the cathode follower *V18*. The zero setting of this circuit is sufficiently stable that the mechanical zero adjustment of the meter suffices to adjust zero. A scale factor adjustment, *R1*, compensates for variations in gain of the first video gain stage and variations of other elements. It is because the meter possibilities are exploited that linearizing feedback is applied to the first video gain stage. Figure 17 shows the peak factor characteristics of the metering circuit.

The second video stage is similar to the first. However, there is no feedback from the output to the input since there is no linearity requirement. In fact, for normal levels the video is completely stripped off the synchronizing pulses at the cathode of *V5*. However, since stabilization occurs at the tops of the synchronizing pulses, the amplifier stages are linear at these instants and there is no danger of clipping the distortion wave carried by the synchronizing pulses. The gas tube, *V6*, reduces the d-c potential to a value near zero for the envelope detector but couples without loss the variations due to input signals. Gas tubes have the characteristic whereby their resistance increases with frequency so that the resistance even at moderately low frequencies is substantially different from the d-c value. For this reason the gas tube must be effectively by-passed at all frequencies within the range of interest, otherwise envelope distortion will be produced in the video gain stages. It is found that a coupling time constant of about 0.25 second neglecting the gas tube will reduce envelope distortion in the gain stages to a negligible value.

V7 and *V9* are the two diodes which, together with r and C, constitute the envelope detector. The output of the second video gain stage is connected to

Figure 17. The video voltmeter peak factor characteristics

the cathode of *V7* while a smaller signal of opposite polarity is connected to the plate of *V9*. The signal of opposite polarity is conveniently obtained from the output of the first video gain stage. A cathode follower, *V8*, is used as the drive for *V9* so that the diode current will not produce distortion at the first video stage output point. The capacitance, across which the envelope voltage appears, is connected through a resistance to the junction of the anode of *V7* with the cathode of *V9*. The resistance-capacitance product of the two elements and the loop gain of the circuit determine the effective time constant of the clamping action.

V10 is a cathode follower to couple the envelope voltage to the grids of the output amplifiers. The output amplifiers are triodes which operate at high current and are coupled to the bridging point with gas tubes and large capacitors. Four tubes are required to handle the peak envelope expected from a 2.5-volt video signal. These tubes are split into two pairs so that tube aging will be more easily detected in maintenance.

The range of levels, which this clamper will handle is nominally 0.2 to 2.5 volts peak-to-peak. The passive elements which shunt the bridge point to ground produce a shunting loss of about 0.8 decibel which is constant over the video band of frequencies. If the impedance irregularity produced by this shunt is undesirable, a T-pad may be constructed by using series resistors in the input and output leads. These resistors of about 7 ohms will provide 75-ohms impedance in each direction and a loss of 1.6 decibels.

Some experiments have been carried out using 75-ohm to 110-ohm transformers at the clamper terminals. With this arrangement signals on balanced 110-ohm circuits may be clamped. Using *197A* repeating coils the clamped output appeared to be free of low frequency distortion. Since the clamper effectively drives the coils with an envelope source impedance approaching zero ohms the low-frequency cut-off of the coils is extended to the point where no video distortion is noticeable.

Conclusions

The effects which result from the use of clampers may be summarized as follows:

Low-frequency interference which adds to the video wave form may be suppressed by a factor inversely proportional to the frequency of the interference. The factor is large, over 30 decibels, at 60 cycles.

The effects of high-frequency interference in the frequency range from 2.5 kc to 100 kc are doubled in amplitude due to the generation of low frequency beats between the interfering frequency and multiples of the video line frequency, (15.75 kc). The amplitude requirement for interference in this range of frequencies is therefore 6 decibels worse with clampers than without. The low-frequency amplitude cut-off requirement of the video system using clampers may be raised in frequency by a factor of 10 to 65 times as compared with a nonclamper cut-off of one to five cycles depending upon the amount of low-frequency gain bump used for 60-cycle phase compensation. Savings are then made in the size of components required for low-frequency transmission.

Transformers as video coupling elements become practicable when clampers are used. The increase of the low-frequency cut-off frequency means that reasonably sized units may be constructed to cover the video transmission band.

Appendix I. Derivation of Envelope

Let the sampling frequency be f_0, and the duration of the sampling time infinitesimally short. Then for an input wave $E=E(n/f_0+t)$ where $0<t<1/f_0$, and n is an integer, the resultant derived wave may be designated by

$$V=E\frac{n}{f_0} \tag{1}$$

and is merely the amplitude of the input wave at the nth sampling interval.

If E is a cosine wave represented by

$$E=\epsilon^{j\omega\left(\frac{n}{f_0}+t\right)}$$

then

$$V=\epsilon^{j\omega\left(\frac{n}{f_0}\right)} \tag{2}$$

If $\omega=2\pi(mf_0+F)$ where m is an integer including zero and $|F|<f_0/2$, then

$$V=\epsilon^{j2\pi\left(m+\frac{F}{f_0}\right)n}=\epsilon^{j2\pi\frac{Fn}{f_0}} \tag{3}$$

since $\epsilon^{j2\pi mn}=1$.

From equation 3 it may be seen that the envelope frequency corresponds not to the input frequency but to the beat between the input frequency and the nearest multiple of sampling frequency including zero.

For the case where the duration of the sampling time is finite, say τ seconds long, let the value of the input wave during the nth sampling time be: $E=E(n/f_0-\tau+t)$ where $0<t<1/f_0$ and as before n is an integer. Further let the resistance-capacitance product of the clamping circuit be T. Then, the envelope after the nth sampling may be represented operationally by

$$V\frac{n}{f_0}=\frac{V\frac{n-1}{f_0}pT+E\left(\frac{n}{f_0}-\tau+t\right)}{1+pT} \tag{4}$$

where $V(n-1/f_0)$ is the value of the envelope derived at the preceding sampling interval, and p is the operator d/dt. The integral equation corresponding to equation 4 is

$$V\frac{n}{f_0}=V\frac{n-1}{f_0}\epsilon^{-\tau/T}+\frac{\epsilon^{-\tau/T}}{T}\times\int_0^\tau E\left(\frac{n}{f_0}-\tau+t\right)\epsilon^{t/T}dt \tag{5}$$

If again E is a cosine wave represented by

$$\epsilon^{j\omega\left(\frac{n}{f_0}-\tau+t\right)},\ 0<t<\frac{1}{f_0}$$

$$V\frac{n}{f_0}=V\frac{n-1}{f_0}\epsilon^{-\tau/T}+\epsilon^{j\omega\frac{n}{f_0}}\left(\frac{1-\epsilon^{-\frac{\tau}{T}(1+j\omega T)}}{1+j\omega T}\right) \tag{6}$$

Since the input is a periodic wave, in the steady state

$$V\frac{n-1}{f_0}=\epsilon^{-j\omega/f_0}V\frac{n}{f_0}$$

and hence, with this substitution in equation 6

$$V\frac{n}{f_0}=\frac{\epsilon^{j\omega n/f_0}\left(1-\epsilon^{-\frac{\tau}{T}(1+j\omega T)}\right)}{(1+j\omega T)\left(1-\epsilon^{-(\tau/T+j\omega/f_0)}\right)} \tag{7}$$

In this instance also, the envelope has the same period as the input wave only if the frequency is less than half the sampling frequency. In only this case is it proper to speak of a residual distortion as being equal to the difference between the input and the envelope. This is given by

$$E\left(\frac{n}{f_0}-\tau+t\right)-V\frac{n}{f_0}=\epsilon^{j\omega\left(\frac{n}{f_0}-\tau+T\right)}\times$$

$$\left[1-\frac{e^{-j\omega(1-\tau)}\left(1-e^{-\frac{\tau}{T}(1+j\omega T)}\right)}{(1+j\omega T)\left(1-e^{-(\tau/T+j\omega/f_0)}\right)}\right] \quad (8)$$

This, in general will have a maximum value at the time just preceding the sampling interval, that is, when $t=1/f_0$. The maximum value of the absolute amplitude of the residual then is defined as

$$R=1-\frac{e^{-j\omega\left(\frac{1}{f_0}-\tau\right)}\left(1-e^{-\frac{\tau}{T}(1+j\omega T)}\right)}{(1+j\omega T)\left(1-e^{(\tau/T+j\omega/f_0)}\right)} \quad (9)$$

When $\omega << f_0$ equation 9 reduces to

$$R=\left[\omega\left(\frac{1}{f_0}-\tau\right)\right]\left[\frac{1}{1-e^{-\tau/T}}+\frac{f_0T}{1-f_0\tau}\right] \quad (10)$$

The second factor of equation 10

$$\left[\frac{1}{1-e^{-\tau/T}}+\frac{f_0T}{1-f_0\tau}\right]$$

is a factor which shows how the clamper time constant reduces the effectiveness of the clamper in reducing low-frequency distortion. It has been plotted in decibels as a function of T in Figure 12. It is identical with an expression equation 16, for the effects of time constant upon the reduction of cut-off distortion.

Values of R against $f=\omega/2\pi$ have been plotted in Figure 8 for the following values of parameters

$f_0=15{,}750$ cycles
$\tau=5$ microseconds
$T=0.8,\ 2.5,\ 10$ microseconds

When $T\to 0$, equation 9 reduces to

$$R\doteq 2\sin\left(\frac{\omega}{2}\left(\frac{1}{f_0}-\tau\right)\right) \quad (11)$$

When $f>f_0/2$, the envelope generated is extraneous and it is proper to speak of it as a new source of interference. As before, let $\omega=2\pi(mf_0+F)$. The beat is then given from equation 7, by

$$V\frac{n}{f_0}=\frac{e^{j2\pi\frac{Fn}{f_0}}\left(1-e^{-\frac{\tau}{T}(1+j\omega T)}\right)}{(1+j\omega T)\left(1-e^{-\left(\frac{\tau}{T}+j\pi F/f_0\right)}\right)} \quad (12)$$

The absolute amplitude of equation 12 may be reduced to

$$A=\sqrt{\frac{(\sinh^2\tau/2T+\sin^2\pi f\tau)}{(1+\omega^2T^2)\left(\sinh^2\frac{\tau}{2T}+\sin^2\frac{\pi F}{f_0}\right)}} \quad (13)$$

Values of A against frequency have been plotted in Figure 11 for the same range in values of T.

Only the first few cyclic variations in A have been plotted. In the region from about 60 to 500 kc, only the values of A when $F=0$ have been indicated. Above 500 kc, only the extreme values obtained when $F=0$, and $\sin(\pi f\tau)=1$ have been shown.

Appendix II. Reduction of Low-Frequency Video Distortion

Where the video signal has been applied to several stages of capacity coupled amplifier stages, or several transformers have been used, the resulting wave form will be characterized by a slope or tilt. This may be analyzed by considering the clamper input as made up of an undistorted signal plus an additional saw-tooth voltage. Then since the clamper leaves the undistorted signal unmodified except for the addition of a d-c component which may be disregarded, the remaining saw-tooth term need only be considered.

It will be assumed for simplicity that this saw-tooth wave is of constant slope and of sufficiently long duration compared to the time of operation of the clamper as to be essentially infinite in duration.

We take as our point of departure equation 5 of Appendix I, and let $E=\alpha(n/f_0-\tau+t)$. Substituting this value of E in equation 5 we obtain after integration

$$V\frac{n}{f_0}=V\frac{n-1}{f_0}e^{-\tau/T}+\frac{\alpha n}{f_0}(1-e^{-\tau/T})+\alpha\tau e^{-\tau/T}-\alpha T(1-e^{-\tau/T}) \quad (14)$$

In the steady-state condition, the increase in envelope voltage in proceeding from one sampling interval to the next must be equal to the corresponding increase in input voltage. That is

$$V\frac{n}{f_0}-V\frac{n-1}{f_0}=E\frac{n}{f_0}-E\frac{n-1}{f_0}=\frac{\alpha}{f_0}$$

Equation 14 may then be reduced to

$$V\frac{n}{f_0}=\alpha\left(\frac{n}{f_0}-T\right)-\alpha\left(\frac{1}{f_0}-\tau\right)\frac{e^{-\tau/T}}{1-e^{-\tau/T}} \quad (15)$$

The maximum value of the residual distortion is then given by

$$R=E\left(\frac{n+1}{f_0}-\tau\right)-V\frac{n}{f_0}=\left[\alpha\left(\frac{1}{f_0}-\tau\right)\right]\times\left(\frac{1}{1-e^{-\tau/T}}+\frac{f_0T}{1-f_0\tau}\right) \quad (16)$$

The second factor in equation 16 indicates the dependence of the residual distortion on the time-constant T, and has been plotted in Figure 12.

Appendix III. Derivation of Envelope for Feedback Loop Clamper

Referring to Figure 14, let $rC=T$. During the nth clamping interval, the output voltage (neglecting Δ) may be represented operationally

$$E_o\left(\frac{n}{f_0}-\tau+t\right)=E\left(\frac{n}{f_0}-\tau+t\right)-\frac{\mu}{1+pT}E_e\left(\frac{n}{f_0}-\tau+t\right)-\frac{E_e\frac{n-1}{f_0}pT}{1+pT}$$

$$=\frac{E\left(\frac{n}{f_0}-\tau+t\right)-\frac{E_e\frac{n-1}{f_0}pT}{1+pT}}{1+\frac{\mu}{1+pT}} \quad (17)$$

Where E_e is the value of the derived envelope across the capacitor C. As in Appendix I, $E_e(n-1)/f_0$ is the value of the envelope for the preceding interval. Then since the difference between the input and output wave is the envelope, we have from equation 17, after the sampling interval

$$E_e\frac{n}{f_0}=\frac{\frac{E_e\frac{n-1}{f_0}p\frac{T}{1+\mu}}{1+p\frac{T}{1+\mu}}+\frac{\frac{\mu}{1+\mu}E\left(\frac{n}{f_0}-\tau+t\right)}{1+p\frac{T}{1+\mu}}}{} \quad (18)$$

Comparing equation 4 we see that it is entirely similar provided we recognize that the effective time-constant has been reduced by the factor $1+\mu$, and that the amplitude of the input is modified by the term $\mu/1+\mu$. Hence we conclude

$$E_e=\frac{\mu}{1+\mu}V \quad (19)$$

Noncontacting Thickness Gauge Using Beta Rays

C. W. CLAPP
NONMEMBER AIEE

S. BERNSTEIN
NONMEMBER AIEE

An earlier paper[1] has described the use of X-rays to measure the thickness of steel as it is being rolled in a hot strip rolling mill. The great success of this method of measurement has stimulated study of the possibilities of using other types of radiation in a similar manner. Of these, beta rays appear to hold the greatest promise at the present time.

Beta rays are electrons emitted spontaneously by certain radioactive materials. Depending on the nature of the source material, these electrons are emitted with maximum energies varying from a few thousand electron volts up to several million electron volts. Those electrons emitted with high initial energy are able to pass through an appreciable thickness of solid material. For example, an electron with an initial energy of 1.3 million electron volts will lose only one half of its energy in passing through a sheet of aluminum 0.038 inch thick.

In principle, it is therefore possible to measure the thickness of a homogeneous sheet of material by placing a source of beta rays at a fixed position on one side of the sheet and measuring the number or the energy of the beta rays which pass through the sheet and reach a detector at a fixed position on the other side. Such a thickness gauge has the important advantage of not requiring physical contact with the sheet being measured. It can therefore be used to measure the thickness of soft uncured rubber or plastic, of textiles or paper coated with soft gummy substances, as well as harder materials such as glass, aluminum, steel and so forth.

Using an ionization chamber as detector, Figure 1 shows the detector current produced by a beam of beta rays after it has passed through different thicknesses of aluminum. The ionization chamber was filled with air at atmospheric pressure, and was provided with an aluminum window only 0.001 inch thick to allow the rays to enter with the minimum of fixed absorption. The thickness of the aluminum absorber is expressed both in inches and in ounces per square yard. Essentially the same curves are obtained for paper, plastic, or rubber, providing the thickness of the material is expressed in terms of its weight per unit area. Since the absorber thickness has been plotted on a logarithmic scale, the slope of the curve is a measure of the change of ionization current for a given small percentage change in the absorber thickness. The range of thickness over which a particular source can be used effectively is limited at each end by loss in sensitivity as evidenced by flattening of the absorption curve.

The source chosen for the gauge to be described consists of strontium 90*. This material gives off beta rays with a maximum energy of 0.65 million electron volts, and has a half-life of 25 years. (The intensity of any radioactive source, as measured by the number of particles emitted per second, falls off exponentially with time. The time required for the intensity of any source to fall to one-half of its initial value is called its "half-life.") With each emission of an electron, an atom of strontium 90 is converted to an atom of yttrium 90. This product material is in turn radioactive, emitting beta rays with maximum energy of 2.16 million electron volts, and has a half-life of 62 hours. Unlike most radioactive materials, no gamma rays accompany the dissociation of strontium 90 or its daughter yttrium 90. This simplifies measurements of the beta ray beam and reduces the amount of shielding needed to prevent stray radiation.

An ionization chamber was chosen as the means to measure the energy in the transmitted portion of the beta ray beam. This detecting means has good stability, does not require high voltages for its operation, and can operate satisfactorily over a wide range of beam intensities. The chamber is filled with air at atmospheric pressure and is sealed to prevent entrance of moisture or other vapors which might adversely affect its operation.

The components of a complete beta-ray thickness gauge are shown in block form in Figure 2. Between the source and the sheet to be measured is a motor-driven chopper or modulator which interrupts the beam 90 times per second. The signal from the ionization chamber is therefore a 90-cycle signal which can be amplified by stable a-c amplifiers, thus avoiding the usual drift problems associated with low-level d-c amplification. To provide an expanded easily-read thickness scale, a potentiometer-type measuring circuit is employed. In this circuit, the output voltage of the ionization chamber is compared with a second 90-cycle voltage of opposite phase which is adjusted in magnitude until the difference between the two voltages is zero. The comparison voltage is derived from a small permanent-magnet alternator driven from the chopper shaft. The attenuator used to adjust the magnitude of the comparison voltage may be calibrated in terms of the thickness or weight per unit area of the material in the beam.

Alternatively, the variable attenuator or gauge dial may be set at the position corresponding to the desired thickness of material to be gauged. The difference be-

Figure 1 (left). Absorption of beta-rays in aluminum

Figure 3 (right). Synchronous rectifier

tween the comparison voltage and the ionization chamber voltage is then a measure of the deviation of the material from the desired thickness.

To read this deviation, the small 90-cycle difference voltage is first amplified by a conventional electrometer tube arrangement. The electrometer tube together with its grid leak and associated circuit components is contained within the sealed ionization chamber to minimize electrical pickup and leakage in the high impedance portions of the circuit. After further amplification, this voltage is then converted to a direct voltage in a synchronous-rectifier type of detector as shown in Figure 3.

Very briefly, its operation is as follows. A constant reference or switching voltage e_r, obtained from the alternator on the chopper shaft is applied through transformer T_1 to two opposite corners of a rectifier bridge. The amplified signal (deviation) voltage, e_s, is applied through transformer T_2 to the remaining two corners of the bridge. The reference voltage has an amplitude from two to three times that of the largest signal voltage, and therefore controls the operation of the rectifier bridge.

During the half cycle of e_r when point A is positive with respect to C, the path ABC is conducting and the path ADC is essentially nonconducting. During this half cycle therefore, the winding HF on transformer T_2 is connected across the load resistance R_L through the two parallel paths $FBAE$ and $FBCE$. Similarly, on the next half cycle of e_r the winding HG is connected across R_L through the parallel paths $GDAE$ and $GDCE$. If e_s contains any 90-cycle component, a direct voltage will be developed across R_L proportional to the component of e_s in phase with e_r.

The output voltage across R_L is applied to a single stage d-c amplifier and thence to a d-c milliammeter calibrated in per cent deviation. The output amplifier is capable of driving up to four such instruments for indicating or recording the thickness deviation.

Since the emission of beta particles from the source is a random phenomenon, the strength of the beam is constant only in a statistical sense. The current in the ionization chamber therefore contains a fluctuating noise component analogous to the "shot" noise current in vacuum tubes. To reduce this noise component and permit easier reading of the deviation indicator, a resistance-capacitance type low-pass filter is inserted in the output circuit. Under these conditions, the rms signal-to-fluctuation-noise ratio (for derivation, see appendix) is approximately equal to $\sqrt{2nT}$, where

n = number of primary beta particles entering ionization chamber per second

T = time constant of single-section low-pass output filter

To reduce the effect of random fluctuations in beam intensity it is apparent that the strength of the source should be as great as possible consistent with economy and safety of operation. Furthermore, the configuration or geometry of the gauge should be such that the radiation detector will intercept as many as possible of the emitted beta particles. When this has been done, the time constant of the output filter may be selected to give the best compromise between high speed of response and low random fluctuations of the deviation indicator.

The beta-ray gauge shown in Figures 4

Figure 2 (below). Block diagram of beta-ray thickness gauge

Figure 4 (right). Beta-ray thickness gauge

and 5 consists of three major units; the gauging head, the operator's panel, and a cabinet containing the electronic control circuits.

The radioactive source, beam chopper, motor, and alternator are mounted in the lower half of the gauging head. The ionization chamber and preamplifier tubes are mounted in the upper half of the head, which is made airtight. On the operator's panel are mounted the deviation indicator, gauge dial, and all other controls necessary to operate and calibrate the gauge. The remainder of the equipment is housed in a separate dust-tight control cabinet.

Over a period of several hours unavoidable drift in the ionization chamber characteristics and in tubes and circuit components may introduce reading errors which must be corrected by recalibration of the gauge. To maintain reading errors below 2 per cent over the normal thickness range of 5 to 150 ounces per square yard, a calibration check is specified at approximately 4-hour intervals.

To check the gauge, all material must first be removed from the throat of the gauge head. The head is normally mounted on a movable slide so that it may be removed easily from a process line for this purpose. A test plate is furnished with the gauge for use in checking calibration.

The gauge dial is normally graduated in arbitrary units. This scale may be replaced by a special scale graduated in terms of the thickness of any desired homogeneous material. Alternatively calibration charts may be used if many widely different materials are to be gauged.

The deviation indicator may be used with auxiliary equipment to control the weight of material passing through the gauge head, or to operate an alarm when the weight exceeds the desired tolerance. Other equipment may be used to return the deviation indicator to zero when there is no material in the beam, allowing more rapid gauging of sections or separate sheets.

Figure 5. Beta-ray thickness gauge (L to R): control cabinet, operator's panel, and gauge head

Appendix. Calculation of Signal-To-Noise Ratio for Ionization Chamber Current

In the following, it is assumed that the current through the ionization chamber consists of a series of short discrete pulses of constant amplitude randomly distributed in time. Actually, of course, the pulse amplitudes vary through a considerable range depending on the energy distribution in the beam of particles reaching the chamber and on other factors related to the absorption process. The results obtained therefore will be only a first approximation to the truth, and will err on the side of predicting a higher signal-to-noise ratio than is justified.

For constant-amplitude pulses, the equation developed for the shot noise in temperature-limited diodes is applicable and we may write

$$i^2 = 2qI\,\Delta f$$

where

i = rms noise current, amperes
q = charge delivered by each constant amplitude pulse, coulombs
I = average chamber current, amperes
Δf = noise bandwidth, cycles per second

hence

$$\frac{I}{i} = \sqrt{\frac{I}{2q\,\Delta f}} = \text{signal-to-noise ratio}$$

Since

$$I = nq$$

where

n = number of primary beta particles entering chamber per second

we may write

$$\frac{I}{i} = \sqrt{\frac{n}{2\,\Delta f}}$$

The noise bandwidth Δf is determined by the transmission characteristic of the output low-pass filter. Let us assume this consists of a single resistance-capacitance section of time constant $T = RC$ seconds. The transmission of such a filter in terms of frequency may be written

$$A = \frac{1}{1 + j2\pi f T}$$

hence

$$\Delta f = \int_0^\infty |A|^2\,df = \int_0^\infty \frac{df}{1 + 4\pi^2 f^2 T^2} = \frac{1}{4T}$$

Therefore, the signal-to-noise ratio is given by

$$\frac{I}{i} = \sqrt{2nT}$$

An Improved Method of Measuring Dissipation Factor and Dielectric Constant Using the Susceptance Variation Principle

C. FRANK MILLER
MEMBER AIEE

FREDERICK G. WHELAN
ASSOCIATE AIEE

THIS paper describes apparatus and techniques which greatly increase the speed and, under certain conditions, the accuracy of the susceptance variation method of measuring dielectric properties. With only slight modification the apparatus is capable of providing a continuous record of the data required to compute the dielectric constant and dissipation factor of solid insulation materials.

The variation of susceptance method of measuring dissipation factor has been described by Hartshorn and Ward.[1] The circuit in its simplest form, Figure 1, consists of an inductance coil and two calibrated standard air capacitors, C_1 which is the specimen capacitor, generally of the parallel-plate type, and C_2 a tuning capacitor, all connected in parallel. A high-impedance vacuum-tube voltmeter is connected so as to measure the voltage across the specimen, and an oscillator loosely coupled to the circuit supplies the voltage.

To measure the dissipation factor of a specimen, the specimen is placed between the plates of capacitor C_1 and the plate separation, d_1 is noted. The capacitor C_2 then is adjusted to give resonance as indicated by a maximum voltage across the specimen. Call the total capacitance at this point C_B, and the voltmeter reading V_B, see Figure 2. The capacitance C_2 then is varied until the specimen voltage drops to some value $V=aV_B$, where a is some number less than 1. Call the total capacitance at this point C_A. The capacitor C_2 then is tuned back through resonance until the specimen voltage again drops to the same value V, this time on the other side of resonance. Let the total capacitance at this setting be called C_B; let $C_A-C_B=\Delta C_1$ be the difference. Capacitor C_2 now is adjusted to the resonant point C_B, and the specimen is removed from capacitor C_1.

With the specimen removed, capacitor C_1 is varied until the voltage across it is again a maximum V_B'. Let this setting of C_1 be called C_0 and its plate separation be called d_2. Again, C_2 is varied until the voltage drops to the value aV_B', where a is the same fraction as before. Let the corresponding values of capacitance be called C_A' and C_B' and their difference $C_A'-C_B'=\Delta C_0$. It can be shown that the dissipation factor D_s of the specimen is given by the formula[1]

$$D_s=\frac{\Delta C_1-\Delta C_0}{(2\sqrt{q}-1)C_0} \qquad (1)$$

where

$$q=\left\{\frac{V_B}{aV_B}\right\}^2=\frac{1}{a^2}$$

The dielectric constant K is obviously the ratio of the plate separation of C_1 with the specimen in place to its plate separation without the specimen. That is

$$K=\frac{d_1}{d_2} \qquad (2)$$

It can be seen that a set of readings by this method not only takes considerable time, but also offers considerable opportunity for error, since five capacitor settings must be read and voltage must be accurately adjusted and read seven times. In order to overcome this difficulty it was decided to use a recording meter to obtain a trace of the resonance curve.

This is done by having a constant-speed motor-driven capacitor tune the circuit through resonance while a recording milliammeter operated from the vacuum-tube voltmeter traces the resonance curve. Limit switches operate relays which reverse the motor at each end of the travel of the micrometer tuning capacitor, so that the circuit is tuned automatically back and forth through resonance until the motor is stopped. During the test itself it is necessary to make only two readings, the settings of the specimen capacitor with and without the specimen in place, and to make only one accurate manual capacitor setting for resonance. The resonance curves can be examined at leisure and the computations can readily be made from them. A permanent record of the test thus is obtained.

Figure 3 shows a cross-sectional view of the resonant-circuit part of the apparatus. The specimen capacitor (4) is a 2-inch diameter parallel-plate capacitor as recommended by the American

Figure 2. Resonance curve nomenclature

Society for Testing Materials,[3] the electrodes being of brass. The upper electrode, which is the ungrounded one, is suspended from the grounded frame by four ceramic cylinders (8) which are 2-inches long by 3/4 inch in diameter. The lower, grounded electrode of the specimen capacitor is mounted on a piece of ceramic tubing (5) which is 2 inches long by $1^1/_4$ inches outside diameter, having a wall thickness of 3/16 inch. The outside of this tube is painted with du Pont ceramic silver coating number *4545*, and copper plated. This method was adopted in order to get low electrical resistance and at the same time low thermal conductance so that heat would not be carried away from the specimen too rapidly at elevated temperatures. The brass electrode is soldered to this copper plating, the other end of the tube being soldered to an Invar rod (6) which is $1^1/_2$ inches in diameter and $2^3/_4$ inches long. This Invar rod is threaded with 40 threads per inch for a distance of $1^1/_2$ inches and threads through a hole in the grounded frame of the apparatus. "Oil dag" is used for lubricating the threads and at the same time, getting good electrical contact between the Invar rod and the frame of the apparatus. Invar was used for the threaded parts so that the material would not expand and jam the threads at elevated temperatures. A 3-inch diameter disk (7) accurately divided around its circumference into 100 divisions is attached to the bottom of the Invar rod beneath the grounded frame of the apparatus so that changes in the spacing of the specimen capacitor may be accurately made to 0.00025 inch.

The known variable (micrometer) capacitor is a cylindrical capacitor mounted directly above the specimen capacitor. The outer, ungrounded electrode (3) is $1^1/_2$ inches long by 5/8 inch in diameter and contains a hole 7/16 inch in diameter, and $1^9/_{16}$-inches deep. The high-voltage electrodes of both the specimen and micrometer capacitors are turned from a single piece of brass so as to eliminate the resistance and inductance of the leads between them. The lower $3^1/_2$ inches of the inner grounded electrode (2) is 3/8 of an inch in diameter, the remainder, except for the top one inch, being threaded with 5/16-40 threads. A 1/4-inch diameter hole approximately 1-inch deep is drilled up through the bottom of the grounded electrode to eliminate capacitance between the bottom of the grounded electrode and the ungrounded electrode, thereby obtaining a more nearly linear relationship between the position of the ungrounded electrode and the capacitance of the micrometer capacitor. A 1/8-horsepower 1,200-rpm motor drives the grounded electrode in or out of the high-voltage electrode by means of a set of reduction gears and a pair of helical gears. The electrode is driven at a rate of 1.6 seconds per revolution which gives a change in capacitance of 8.76 micromicrofarads per minute.

The same motor which drives the micrometer capacitor also drives a small worm gear. This worm gear has a pin driven into it which trips a limit switch just before the micrometer capacitor has reached the end of its travel in either direction. This limit switch operates a set of relays which: stops the motor; applies a brake (a 1/10-horsepower d-c motor operated as a separately-excited generator with a very low resistance load across its armature); removes the brake after the motor has slowed down sufficiently; and starts the motor in the opposite direction. The wiring diagram of this relay system is shown in Figure 4. Thus, if the midpoint of the micrometer capacitor travel is the resonant point, the circuit will automatically be tuned back and forth through resonance continuously.

The inductance consists of a coil of $9^1/_2$ turns of 1/4-inch copper tubing, the coil having an average diameter of $2^3/_4$ inches. One end of this coil is directly connected to the grounded frame. The tuning capacitor is an ordinary variable air capacitor having a maximum capacitance of 175 micromicrofarads. Figure 5 is a wiring diagram of the resonant circuit, oscillator, and voltmeter.

The micrometer and specimen capacitors are mounted within a frame, Figure 3, 6-inches wide and $5^3/_4$-inches high and 3-inches deep, the pieces being 7/16-inches thick, and made of Invar so that their lengths will not change with temperature.

A smaller cast iron framework fits on top of the main one so as to enclose the gear which drives the movable electrode of the micrometer capacitor. The threaded bushing on which this gear is mounted and keyed enables the electrode to be driven up and down without turning. In order to prevent turning of this electrode, a pin driven horizontally through the electrode at its top protrudes through a vertical slot cut in a brass tube fastened on top of the upper frame concentric with the movable electrode. A brass bushing $1^1/_2$-inches long mounted in the upper horizontal member of the main ground frame eliminates any possible wobble of the movable electrode of the micrometer capacitor as it travels up and down.

Figure 3. Sectional view of motor-driven micrometer capacitor assembly

Twenty-four ounce sheet copper is used throughout for shielding. One shield completely encloses the coil, while a second shield encloses the three air capacitors. The front of the shield is divided into three sections, the central one of which is hinged so as to allow specimens to be inserted and removed readily. The high-voltage lead from the generator also is shielded. The voltmeter terminals protrude through holes in the front shield. These terminals are of copper tubing, the ungrounded one being screwed into the upper (ungrounded) plate of the specimen capacitor while the ground terminal is screwed to the grounded frame.

The voltage across the specimen is measured with a General Radio type *726-A* vacuum-tube voltmeter. In order to record the voltage, the meter circuit of the vacuum-tube voltmeter was opened

Figure 4 (left). Motor control circuit

Figure 6 (above). Schematic of amplifier

and a 2,500-ohm resistor was inserted. This was made the grid-leak resistor of a single-stage d-c amplifier, Figure 6, using a *6J5* tube biased at -1.5 volts with a plate supply of 90 volts. A 1-milliampere Esterline-Angus recording meter model *AW* is connected in the plate circuit and a compensating circuit is used to balance out the normal plate current so that the recorder reads zero when no voltage is applied to the vacuum-tube voltmeter. Although this amplifier is not perfectly stable, it is quite satisfactory since the zero point can be checked and adjusted readily at frequent intervals.

Voltage is supplied to the resonant circuit from a 1-kilowatt Westinghouse industrial high-frequency generator style *867692*. The oscillator is loosely coupled to the resonant circuit by means of capacitive coupling, so that the frequency of the oscillator remains constant during a test and so that the oscillator presents practically infinite impedance to the resonant circuit.

The chart speed used gives a curve width (for $V/V_r = 0.707$) of approximately 0.5 inch for air, and curve width of approximately 0.5 inch to 6.0 inches for various specimens tested. There appears to be a very slight lag in the response of the recorder at this speed, but it apparently does not affect the results, since several results were checked almost exactly by the familiar indicating voltmeter and hand-operated capacitor method.

Calibration of Apparatus

In order that the apparatus give an accurate measurement of dissipation factor and dielectric constant, it is necessary that the several components be calibrated.

The specimen capacitor was calibrated with a Bendix capacitor checker employing the beat-note principle. A plot of the calibration data is shown in Figure 7. Here the measured value of total capacitance has been plotted against $1/t$ where t is the spacing of the specimen capacitor in inches. The computed geometric capacitance (neglecting edge and stray effects) is plotted on the same set of axes. It can be seen that the measured total capacitance gives a straight line parallel to that of the computed geometric capacitance for values of t greater than 1/32 inch. This means that the sum of the stray capacitance and edge-effect capacitance is a constant for the working range of the apparatus and can be considered to be a part of the tuning capacitance and ignored. This calibration was made with the tuning capacitor and the micrometer capacitor both set at their minimum capacitance positions. The capacitance of these two elements is considered as part of the stray capacitance. If the tuning capacitor had been set near the middle of its range as it frequently is during the measurement of a specimen, then its constant capacitance would obscure the small variations in the edge effect capacitance even more completely.

The micrometer capacitor must be perfectly linear over its working range. Its calibration was accomplished by the procedure employed in the calibration of the specimen capacitor, using a type *222* General Radio precision air capacitor as a standard. In Figure 8 the capacitance of the standard capacitor is plotted against the position of the grounded electrode. Only the central portion of the capacitor range is used on any of the specimens reported on in this paper, and here the micrometer capacitor is seen to be almost perfectly linear. This calibration was checked several times with almost identical results. The average change in capacitance of the micrometer capacitor was found to be 9.35 micromicrofarads per inch of electrode travel. This is quite close to the computed value of 9.16 micromicrofarads per inch.

The micrometer capacitor is driven at a rate of 1.6 seconds per revolution of the driving gear; and since there are 40 threads per inch on the electrode shaft, the driving rate is 64 seconds per inch of electrode travel. This gives a rate of change of capacitance of 9.35/64 or 0.1461 micromicrofarads per second, or 8.76 microfarads per minute.

The chart of the Esterline-Angus recorder is driven at a rate of $6^1/_2$ inches per minute. Thus the rate of change of capacitance with respect to chart speed is found to be

$\Delta C = 1.43$ micromicrofarads per inch of chart travel

It was next necessary to check the recording voltmeter. In the susceptance-variation method, it is not necessary to read any actual voltages, but the ratio of two voltages must be known. This means that if the device used to indicate the specimen voltage does not actually

Figure 5. Wiring diagram of resonant circuit, oscillator, and voltmeter

Figure 7 (left). Specimen capacitor calibration data plot

Figure 9 (above). Calibration curve for recording voltmeter and amplifier

measure this quantity in volts, it must at least have a constant characteristic, preferably linear or square-law, over its entire range.

In this apparatus the amplifier was so designed that the deflection of the recording meter is directly proportional to the specimen voltage. The results of the calibration of the recording meter are shown in Figure 9. The calibration was made with a second General Radio type *726A* vacuum-tube voltmeter, since the indicating meter of the vacuum-tube voltmeter used to drive the amplifier does not read quite correctly because of the additional 2,500-ohm resistor connected in series with it. Figure 9 shows that the recording meter gives a deflection directly proportional to the specimen voltage.

Description of Tests

A total of 35 specimens was used in the work reported in this paper. Of these, four were glass and the remainder were plastics. There were three specimens each of ten different plastics and a single specimen of an eleventh plastic. This single specimen was molded thermosetting material, two other materials were rigid thermoplastics and the remainder were laminated thermosetting materials. The specimens were all 2.000 ± 0.005 inch in diameter and the plastics ranged in thickness from 0.110 to 0.132 ± 0.002 inch, while the glass specimens were 0.246 to 0.248 ± 0.002 inch thick.

In preparing the specimens, the American Society for Testing Materials standards[3] were followed as closely as possible. Electrodes made of lead foil 0.003-inch thick were used. These electrodes were affixed with a very thin film of petrolatum and rolled down until no visible imprint could be made on the surface with the roller. Both electrodes were of the same diameter as the specimen.

All specimens were kept in desiccators containing a solution of NH_4NO_3. This kept the humidity within the desiccators at 63 per cent, which is approximately the average room humidity during the tests. The specimens were run at normal room temperatures which ranged from 76 to 81 degrees Fahrenheit.

Before starting a test, the oscillator, vacuum-tube voltmeter, and amplifier are warmed up for several minutes, and the micrometer capacitor is set at the center of its travel.

The first specimen then is removed from its desiccator and inserted in the specimen capacitor, the lower plate of this capacitor is screwed up tight against the specimen, and the capacitor spacing is noted. The copper shield is closed, and the vacuum-tube voltmeter is plugged in across the specimen.

The plate voltage of the oscillator then is turned on, the tuning capacitor is ad-

Figure 8 (below). Calibration curve for micrometer capacitor

Figure 10 (right). Samples of recorded resonance curves

justed so as to get maximum voltage across the specimen, and this maximum voltage is adjusted at the oscillator to some convenient value. A resonant voltage of approximately 50 volts was always used, both for air and for the specimens. The vacuum-tube voltmeter then is disconnected and short-circuited, the micrometer capacitor driving motor is started, the recording chart drive is turned on, and the amplifier is adjusted until the recorder reads zero. The vacuum-tube voltmeter then is connected across the specimen again. All this is done while the micrometer capacitor is being driven from its midpoint to its all-in or maximum position. It is not necessary to check the zero point before each specimen is tested, but it should be done occasionally because the amplifier has a small drift.

When the micrometer capacitor reaches its all-in position the motor reverses, decreasing the capacitance of the micrometer capacitor. As the capacitor is driven to its all-out or minimum position, the circuit is tuned through resonance and the recorder traces out the resonance curve on its chart. Typical resonance curves for a specimen and for air are shown in Figure 10.

As soon as the micrometer capacitor reaches its all-out position the motor again is reversed, driving the capacitor back to resonance. When the resonant point is reached, the motor is stopped, the oscillator voltage is reduced, and the specimen is removed from the specimen capacitor. The specimen capacitor then is adjusted to give voltage resonance, the micrometer capacitor driving motor and chart are started, and the resonance curve for air is obtained.

After the specimens are all tested, the chart is removed from the recorder and examined. First the two points on each curve where the voltage dropped to 0.707 V_R are marked. (q was made equal to two throughout the tests so as to simplify the calculations.) The width of each curve at the 0.707 V_R marks then is measured to the nearest 0.01 inch. Knowing the width of the specimen curve, ΔC_t, the width of the air curve, ΔC_0, and the capacitance C_0 of the specimen capacitor after the specimen has been removed and the capacitor has been readjusted to resonance, the dissipation factor of the specimen, D_s, can be computed readily from equation 1. If we let W_t and W_0 be the widths of the specimen and air resonance curves, measured in inches, and d_2 be the spacing of the specimen capacitor, in revolutions (1 revolution = 1/40 inch) after the specimen has been removed, then the equation reduces to

$$D_s = 0.0253\,(W_t - W_0)d_2 \qquad (3)$$

As has been stated previously, the dielectric constant of the specimen is given by the equation

$$K = \frac{d_1}{d_2} \qquad (2)$$

where d_1 = spacing of specimen capacitor with the specimen in place, and d_2 = spacing of specimen capacitor with the specimen removed and the capacitor retuned for resonance.

Each specimen was tested five times at 24-hour intervals, in order to get an average value of the dissipation factor and dielectric constant. Since an attempt was made to take all of the measurements under identical conditions, an idea of the reproducibility of the results for specimens of various dissipation factors and dielectric constants is obtained.

Discussion of Results

An examination of the results of the five tests on each specimen showed that the values of dielectric constant, K, could be reproduced quite accurately for every specimen. For most specimens the dissipation factor, D_s, also was reproduced quite closely.

In order to get a better idea of how closely the results could be repeated, the averages of the five values of K and D_s for each specimen were calculated. The deviation of each of the five original results from this mean value was found, and the average of these five deviations from the mean was calculated for each specimen. Table I shows for each specimen

the average or mean value of K and D_s, and the average deviation from this mean value expressed first as a pure number and then as a percentage of the mean. The average of the mean values of K and D_s for the three specimens of each material was found, so as to get an average value of K and an average value of D_s for each material. These values are shown in Table I.

For all values of dielectric constant found, ranging from 3.0 to 7.3, the average deviation from the mean was always less than 0.1, and it was less than 0.05 in all but a few cases. The higher deviations from the mean occur where the capacitance of the specimen capacitor was highest. This can be seen from the fact that for 1/8-inch plastic specimens the deviation becomes large for values of K above 5, while for the 1/4-inch glass specimens excellent results are obtained even though the value of K is above 7. Comparatively large deviations in the value of K are believed to be due to the fact that the capacitance of the specimen capacitor changes rapidly with small changes in the electrode spacing when the spacing is small and therefore the capacitance cannot be read as accurately as it can be for larger spacings.

The values of dissipation factor could not be reproduced so well as those of dielectric constant. The results are still quite good, however. Only in the case of glass are the percentage errors large and here the average deviations are quite small, being less than 0.005 in every case. At the 0.707 point where the widths of the curves were measured, the curves for glass and the curves for air differed by only slightly more than 0.1 inch. Since the curves could be measured only to the nearest 0.01 inch, a percentage error of about 10 per cent is to be expected. In the case of specimens 28, 29, and 30, the per cent deviation also is rather high, but here again it is because the dissipation factor of that material is so low rather than because the deviations themselves are high. In most cases the per cent average deviation is about 2 per cent or less, which is quite good for all but the most precise work.

In general it appears that the higher the dissipation factor, the higher the average deviation is. It is believed that the variations are in the specimens rather than in the apparatus. It seems reasonable to suppose that if the loss component of current is quite small, variations in it will be smaller than in the case of a larger loss component. It is felt, with several exceptions, that one measurement is just as accurate as another for all of the specimens discussed here.

Figure 11. Plot of data required to check shape of recorded resonance curves

The results on specimen 37 are not so good as they might be because this material is really slightly out of range of the apparatus. Its dissipation factor is so high that its resonance curve did not drop to 0.707 times the maximum value. A q of 1.64 rather than 2 had to be used in calculating its dissipation factor.

In order to determine whether the resonance curves obtained conformed to the theoretical resonance curve, the method proposed by Sinclair[3] was tried. This consists of plotting $\sqrt{q-1}$ against the change in capacitance for a number of points on the resonance curve. The dissipation factor for the resonant combination is given by

$$D=\frac{\Delta C}{2C_s\sqrt{q-1}}$$

Here C_s is the total shunt capacitance at resonance and ΔC is the width of the resonance curve corresponding to the value of q used. Since D and C_s are constant for any one run, $\sqrt{(V_R/V)-1}$ must be proportional to ΔC. Hence, if we plot $\sqrt{q-1}$ against ΔC, we should get a straight line having a slope of $1/(2C_sD)$, or W/G.

This was tried for several resonance curves picked at random. Such a plot is shown in Figure 11, where the points lie almost exactly along a straight line. This shows that the curve traced out by the recording meter is a true resonance curve and that no appreciable error results from measuring the widths of the resonance curves only at the 0.707 point rather than at several points. Sinclair points out that for most accurate results all data should be plotted in this way and that the slope of the best straight line through all of the points be used in computing D. No doubt the accuracy of the results here presented could be increased somewhat by this method, but the improvement would apparently not warrant the additional time and work.

Modification to Permit Continuous Recording of Dielectric Constant and Dissipation Factor Data

This apparatus can be modified easily to obtain a continuous record of the data required to calculate the dissipation factor and dielectric constant. With constant chart speed, such data will be plotted against time as abscissa. If the corresponding temperature-time characteristic of the sample is obtained by a separate record, complete data for the "temperature versus dielectric constant" and "temperature versus dissipation factor" characteristics are obtained.

The only modification required in the apparatus is the addition of a means of providing a marker "pip" or "dent" in the voltage record to indicate a position of the micrometer capacitor at which its capacitance is known.

Conclusions

1. A recording device for measuring dissipation factor and dielectric constant by the susceptance-variation principle has been built. The performance of this apparatus has been investigated, and it has been found to be very satisfactory and reliable. Its use results in a great saving in time and care in making such measurements.

2. The dissipation factor and dielectric constant of a total of 31 specimens of 11 commercial plastics and four specimens of glass have been measured by this apparatus. These measurements were made at room temperature at a frequency of 10 megacycles per second, using a stress of the order of 0.2 to 0.4 volt per mil.

3. The results of these measurements

have been analyzed to determine the approximate accuracy of the apparatus. For 1/8-inch plastic specimens having dielectric constants ranging from 2.99 to 6.47, the maximum value of the average deviation from the mean of five measurements was 0.094, and 1.70 per cent. For dissipation factors ranging from 0.0128 to 0.0666, the maximum value of the average deviation was 0.00232, and 4.89 per cent. Most deviations were considerably smaller than these.

4. The effect of extensive screening of the apparatus on the accuracy of the results has been studied. The screening apparently added some losses to the system while eliminating others, and the width of the resonant curve was found to be essentially the same with and without screening. The screening was found to aid greatly in eliminating slight wiggles in the resonance curves, however, and thus increased the accuracy of the results.

5. The method presents many advantages for the routine measurement and control of large numbers of commercial and industrial samples.

An Analysis of Transients in Magnetic Amplifiers

Synopsis: Analytical expressions are developed for the envelope of the transient output current of a magnetic amplifier when the control voltage is varied. The magnetization curve of the core material is expressed in a convenient analytical form and the differential equations of the system are integrated under certain simplifying assumptions. The analysis applies to transients lasting a few cycles of the supply frequency, or longer; and experimental checks show good agreement within the range of transients specified above. The results are given in the form of dimensionless curves expressing the average flux density, average magnetizing intensity, and output currents as functions of time. Thus the influence of the core material and of factors of design upon the transient response of the amplifier are determined.

THE steady-state theory of interlinked electric and saturable magnetic circuits (as they occur in magnetic amplifiers) has been given in a number of recent papers.[1,2,3,4] The transient response to a sudden change in control circuit conditions has been described qualitatively,[4,5] but no quantitative analysis has been published heretofore. The purpose of this paper is to give such a study, limited in the present work to configurations without feedback. To illustrate the method, it is assumed that the transient is initiated by suddenly closing the control circuit through a battery, the load impedance being zero.

Paper 50-76, recommended by the AIEE Electronics Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted July 8, 1949; made available for printing December 2, 1949.

Method and Assumptions

The method of analysis is an extension of that already given for the steady state.[1,3,4] Briefly it is to apply Kirchhoff's voltage law to the electric circuits, Ampere's line integral law to the magnetic circuits and to use the normal magnetization curve expressed in some convenient analytical form to relate currents and flux densities. In doing this it is assumed that sinusoidal voltage is impressed directly on the amplifier terminals and thus effects of load impedance are neglected. Other simplifications are to ignore leakage fluxes, hysteresis, and eddy currents. In the steady-state analysis all resistances are assumed small although not neglected entirely. In the transient analysis this necessarily is modified as will be seen by taking control circuit resistance more fully into account.

If one assumes that sinusoidal voltage is impressed on the a-c terminals of a magnetic amplifier and neglects the impedance of the control circuit to harmonic currents, one finds in the steady state that the flux density in each of the cores varies sinusoidally about an average or direct component of flux density B_0 which is the same for both cores. Moreover it is found that this "d-c flux density" is not a simple function of the direct control current alone, as one might think, but also depends on the magnitude of the superimposed alternating flux density which is required to sustain the impressed alternating voltage. In the steady state it is found that the magnetomotive force acting on each core is expressible as a Fourier series having a term of fundamental frequency, both odd and even harmonic terms, and a constant term referred to, in what follows, as the direct component. In the circuits studied it is found, as would be expected, that the current flowing in the load consists only of the fundamental and odd harmonics, and that only a direct component and even harmonics flow in the control circuit.[4]

For every steady state determined by a value of control current and a value of impressed a-c voltage there corresponds a value of B_0. If the control current or a-c voltage or both are changed, B_0 must in general change to a new value for the new steady state. Thus any study of transient behavior must be concerned primarily with the growth or decay of B_0 as also has been noted by others.[3]

The present treatment is limited to cases where a transient of appreciable magnitude persists for at least several cycles of the applied alternating current, as in fact is usually the case in practice. This makes it reasonable to focus attention on the transients in the direct components of the various quantities and to assume that the alternating components at any instant have the magnitude determined from steady-state relationships using the value of B_0 for the instant in question. The legitimacy of this approxi-

Figure 1. Series-connected magnetic amplifier ($i_L = i_2$)

Figure 2. Normal magnetization curve and its analytical representation

Figure 4. Transients of the direct component of flux density shown in dimensionless form for the circuits of Figures 1 and 3

mation has been checked by making several step-by-step integrations of the circuit equations for a number of configurations, and also it results in satisfactory over-all checks with experiments, as will be shown later on in the paper.

Series-Connected Magnetic Amplifier

As a first example, a transient analysis will be made of the magnetic amplifier with output coils connected in series, shown in Figure 1.

The analysis starts by assuming that one can express the instantaneous flux densities in the cores B_α and B_β respectively by

$$B_\alpha = B_m \sin \omega t + B_{0t} \tag{1}$$
$$B_\beta = -B_m \sin \omega t + B_{0t} \tag{2}$$

These expressions are exactly like those which have been developed for the steady state[1,3,4] except that here the direct component of flux density B_{0t} is not a constant but may vary in time, a fact denoted by the second subscript, t. As in the steady-state case and using meter-kilogram-second units, $B_m = E_m/2N_2A\omega$ where E_m and ω are respectively the crest value and angular frequency of the applied a-c voltage (assumed constant throughout the transient), A is the cross-sectional area of each core and N_2 is the number of turns in each output coil.

Application of Kirchhoff's voltage law to the control circuit gives

$$E_{dc} = 2R_1 i_1 + N_1 A \frac{d}{dt}(B_\alpha + B_\beta) \tag{3}$$

Here E_{dc} is the control battery voltage and $2R_1$ is the entire resistance of the circuit, represented by R in the figure. Then substituting equations 1 and 2 in equation 3, and considering only the direct components one obtains

$$E_{dc} = 2R_1 I_{1t} + 2N_1 A \frac{dB_{0t}}{dt} \tag{4}$$

where I_{1t} is the direct component of i_1. Upon separation of variables, the time t for the direct component of flux density to change from an initial value B_{00} to another value B_{0t} may be written as

$$t = \frac{N_1^2 A}{R_1} \int_{B_{00}}^{B_{0t}} \frac{dB_{0t}}{N_1 I_{1\infty} - N_1 I_{1t}} \tag{5}$$

Here use has been made of the fact that the final ($t = \infty$) value of control current $I_{1\infty}$ and the battery voltage E_{dc} are related by $E_{dc} = 2R_1 I_{1\infty}$.

To evaluate the integral in equation 5, one must have a relationship between B_{0t} and $N_1 I_{1t}$. This relationship for the steady state is dependent on B_m, the magnitude of the alternating flux density, and is obtainable from the normal magnetization curve as shown elsewhere.[1,4] It is assumed here that this steady-state relationship also holds in the transient case. Evaluation of equation 5 then can be carried out graphically by well known procedures.[7]

Figure 3. Parallel-connected magnetic amplifier ($I_L = i_2 + i_3$)

To carry out the integration analytically, the normal magnetization curve must be expressed in analytical form, and for this the relation

$$H = U \sinh uB \tag{6}$$

is used, which permits relatively simple integrations. Here H is the magnetic field intensity, B is the flux density and U and u are constants determined by the shape of the magnetization curve. This function fits well enough to yield satisfactory transient results for common core materials such as hypernik and silicon steel. The fitting for the hypernik used in the experimental checks is illustrated in Figure 2. Again, as in the steady-state treatment, use is made of Ampere's circuital law to relate currents and magnetic field intensities, thus

$$N_1 i_1 + N_2 i_2 = LH_\alpha \tag{7}$$
$$N_1 i_1 - N_2 i_3 = LH_\beta \tag{8}$$

where H_α and H_β are the magnetizing intensities in cores α and β respectively and L is the mean length of magnetic path per core. H_α and H_β are found by substitution of the flux densities as given by equations 1 and 2 into the function, equation 6, representing the B-H curve. The results are Fourier series each containing both odd and even harmonic terms and a constant, or direct component which is the same for both cores.[4] As already explained the direct component for purposes of this study is considered to vary during the transient. Substitution of the series for H_α and H_β into equations 7 and 8 yields the following relation between direct components

$$N_1 I_{1t} = LH_{0t} \tag{9}$$

where H_{0t} is the direct component of either H_α or H_β and is given by

$$H_{0t} = U\mathcal{J}_0(uB_m) \sinh uB_{0t} \tag{10}$$

where $\mathcal{J}_0(uB_m)$ is the modified Bessel

Figure 5. Transients of the direct component of magnetic intensity shown in dimensionless form for the circuits of Figures 1 and 3

Figure 6. Envelopes of the output current i_L shown in dimensionless form for the circuits of Figures 1 and 3

function of the first kind of zero order.[6]

Substitution of equation 9 in equation 5 results in

$$t=\frac{N_1^2A}{R_1}\int_{B_{\theta 0}}^{B_{\theta t}}\frac{dB_{\theta t}}{N_1I_{1\infty}-LH_{\theta t}} \tag{11}$$

and further substitution of equation 10 permits evaluation of the integral.

For the case where $B_{\theta 0}$ is initially zero, that is, the control circuit is initially open (and there is no residual) and then suddenly closed at $t=0$, the result is

$$\frac{t}{\tau_s}=\tanh uB_{\theta\infty}\tanh^{-1}\left\{\frac{\tanh\dfrac{uB_{\theta t}}{2}}{\tanh uB_{\theta\infty}-\operatorname{sech} uB_{\theta\infty}\tanh\dfrac{uB_{\theta t}}{2}}\right\} \tag{12}$$

where τ_s, a quantity having the dimensions of time, is given by

$$\tau_s=\frac{4N_1A}{uE_1}=\frac{2N_1A}{uR_1I_{1\infty}}=\frac{2N_1^2A}{LR_1U_p u\mathfrak{J}_0(uB_m)\sinh uB_\theta} \tag{13}$$

and $B_{\theta\infty}$, the final ($t=\infty$) value of the direct component of flux density, is given by

$$uB_{\theta\infty}=\sinh^{-1}\left(\frac{N_1I_{1\infty}}{LU\mathfrak{J}_0(uB_m)}\right) \tag{14}$$

Equation 12 also may be solved explicitly for $B_{\theta t}$ as a function of time

$$uB_{\theta t}=2\operatorname{ctnh}^{-1}\left\{\operatorname{ctnh} uB_{\theta\infty}\operatorname{ctnh}\left[\frac{t}{\tau_s}\operatorname{ctnh} uB_{\theta\infty}\right]+\operatorname{csch} uB_{\theta\infty}\right\} \tag{15}$$

Equation 15 gives in dimensionless form the transient of the direct component of flux density and is valid for any core material which equation 6 can be made to fit.

Equation 10 gives the transient of the direct component of magnetizing intensity $H_{\theta t}$ upon substitution of the value for $B_{\theta t}$ from equation 15. This is conveniently expressed as a ratio of the transient value to final steady state value $H_{\theta\infty}$ by

$$\frac{H_{\theta t}}{H_{\theta\infty}}=\frac{\sinh uB_{\theta t}}{\sinh uB_{\theta\infty}} \tag{16}$$

By virtue of equation 9 the transient of the direct component of control current in the series-connected magnetic amplifier is also given in dimensionless form by equation 16.

To find the transient of the output current, equations 7 and 8 are solved simultaneously for the output circuit ampere-turns, giving

$$N_2i_2=\frac{L}{2}[H_\omega-H_\theta]=L[H_1\sin\omega t+H_3\sin 3\omega t+H_5\sin 5\omega t+\ldots] \tag{17}$$

where the harmonic coefficients[4,8] are

$$\begin{aligned}H_1&=2u\mathfrak{J}_1(uB_m)\cosh uB_{\theta t}\\ H_3&=-2u\mathfrak{J}_3(uB_m)\cosh uB_{\theta t}\\ H_5&=2u\mathfrak{J}_5(uB_m)\cosh uB_{\theta t}\end{aligned} \tag{18}$$

Therefore the transient of output current, also expressed in a ratio, is given by

$$\frac{i_{Lt}}{i_{L\infty}}=\frac{\cosh uB_{\theta t}}{\cosh uB_{\theta\infty}} \tag{19}$$

where i_L, the output current is equal to i_2. As a consequence of the representation chosen for the magnetization curve, equation 19 applies alike for peak, rms, and rectified average values.

Parallel-Connected Magnetic Amplifier

The second configuration considered is the magnetic amplifier with output coils connected in parallel as shown in Figure 3.

In the steady state, no direct current components can flow in the output windings, and the direct component of magnetizing intensity is wholly supplied by the control direct current. During a transient, however, if the control circuit is suddenly energized, direct components of current do flow in the outside series loop of the output windings in agreement with the requirements of the constant flux linkage theorem. Thus, upon closing the switch, the control current exhibits a jump while the current in the series path through the output coils jumps in the opposite direction, the magnitudes being determined by the relative resistances and turn ratios. Thus in the calculation of the transient, two paths for the flow of the direct com-

Figure 7. Oscillograms comparing transients for series and parallel connections

The upper trace is control current and the lower, output current

Figure 8. Calculated envelopes of output current in dimensionless form compared with points measured from the oscillograms of Figure 7

ponents of currents must be considered.

The flux density again is assumed to vary sinusoidally with time about a d-c value B_{0l} and consequently equations 1 and 2 also apply for this case except that here $B_m = E_m/N_2A\omega$.

Application of Kirchhoff's voltage law to the control circuit and to the circuit through the output coils in series, Figure 3, results in

$$E_{dc} = 2R_1i_1 + N_1A\frac{d}{dt}(B_\alpha + B_\beta) \tag{20}$$

$$0 = R_2(i_2 - i_3) + N_2A\frac{d}{dt}(B_\alpha + B_\beta) \tag{21}$$

where R_2 is one-half of the total series resistance of the outside loop and the other symbols are as before.

Substituting equations 1 and 2 in equations 20 and 21, replacing instantaneous values by their Fourier series components results in the following relations between the direct components

$$E_{dc} = 2R_1I_{1l} + 2N_1A\frac{dB_{0l}}{dt} \tag{22}$$

$$0 = R_2(I_{2l} - I_{3l}) + 2N_2A\frac{dB_{0l}}{dt} \tag{23}$$

where I_{2l} and I_{3l} are the direct components of i_2 and i_3 respectively.

From application of Ampere's line integral law one obtains the instantaneous relationships

$$N_1i_1 + N_2i_2 = LH_\alpha \tag{24}$$

$$N_1i_1 - N_2i_3 = LH_\beta \tag{25}$$

from which follow the corresponding relationships among the direct components

$$N_1I_{1l} + N_2I_{2l} = LH_{0l} \tag{26}$$

$$N_1I_{1l} - N_2I_{3l} = LH_{0l} \tag{27}$$

Simultaneous solution of equations 22, 23, 26, and 27 leads at once to

$$t = \left[1 + \left(\frac{N_2}{N_1}\right)^2\frac{R_1}{R_2}\right]\frac{N_1^2A}{R_1} \times \int_{B_{0l}}^{B_{0l}} \frac{dB_{0l}}{N_1I_{1\infty} - LH_{0l}} \tag{28}$$

which is identical with equation 11 except for the presence of the constant multiplying factor in square brackets. Since equation 10 applies here also, except that now $B_m = E_m/N_2A\omega$, the integration is carried out as in the series case and the result is the same except that the time scale factor τ_s is replaced by a new time scale factor given by

$$\tau_p = \left[1 + \left(\frac{N_2}{N_1}\right)^2\frac{R_1}{R_2}\right]\tau_s = \frac{2N_1A}{uI_{1\infty}} \times \left[\frac{1}{R_1} + \left(\frac{N_2}{N_1}\right)^2\frac{1}{R_2}\right] \tag{29}$$

Therefore equations 12 through 19 defining the transient behavior of the series magnetic amplifier apply also for the parallel case except for modification of the time scale factor in accordance with equation 29.

In the parallel case the output current i_L is $i_2 + i_3$.

In the parallel case the transient in the direct component of control current is different from that in the series case. As already pointed out, there now is an initial jump in the control current when the control circuit is suddenly energized and a corresponding jump in the direct component of current which circulates in the series circuit through the two output coils. These initial currents are found using equations 22 and 23 and the condition that the flux linkages of each of the two circuits in question cannot change instantaneously.

The results are

$$I_{10} = \frac{E_{dc}}{2R_1 + 2R_2\left(\frac{N_1}{N_2}\right)^2} \tag{30}$$

$$I_{20} = -I_{30} = -\frac{N_1}{N_2}I_{10} \tag{31}$$

The direct component of control current I_{1l} then increases gradually from I_{10} to $I_{1\infty}(=E_{dc}/2R_1)$ while I_{2l} and $_3I$ decay to zero.

Discussion of Analytical Results

From the foregoing analysis it is apparent that the transient variation of the direct component of flux density B_{0l} has great importance since it determines the transient behavior of the currents. B_{0l} is given by either of equations 12 or 15 and is plotted in dimensionless form in Figure 4 for different values of the parameter uB_{0m}. This parameter is, as shown by equation 14, a function of the final steady-state control current, $I_{1\infty}$, and of B_m, which is determined by the applied a-c voltage. Thus the curves given in Figure 4 are general and usable for series or parallel-connected amplifiers whose core materials have normal magnetization curves representable by equation 6. For the series case the time t to reach any specified value of B_{0l} depends on a factor τ_s which has the dimensions of time and is somewhat analogous to the time constant of a simple linear L-R circuit. However this time factor τ_s is not a constant as in the linear case since it depends, as shown by equation 13, not only on the design constants of the control winding and core but also on the magnitude of the driving voltage E_{dc}. τ_s is not dependent in any way on quantities associated with the a-c circuit; these quantities enter in the determination of B_m and therefore of uB_{0m} as shown in equation 14.

It is significant that Figure 4 also applies to the parallel case except for the replacement of τ_s by another time factor τ_p which depends in addition on the number of turns and resistance of the output coils as shown in equation 29. If a series-connected magnetic amplifier has its output coils reconnected in parallel and the a-c voltage reduced to half its former value, the steady-state performance will remain unchanged except for a doubling of the load current since B_m and B_0 will remain the same for equal control currents.[1] Such a change, however, will always slow down the transient response since, as may be seen from equation 29, the time scale factor will be reduced. For example, if $R_1 = R_2$ and $N_1 = N_2$, then $\tau_p = 2\tau_s$ and the transient response with

the parallel connection will be just twice as long as with the series connection.

Figure 5 shows dimensionless plots of the transient of the direct component of magnetic intensity plotted from equation 16. Of greater practical interest is Figure 6 in that it shows the transient in the output current, again in dimensionless form, as obtained from equation 19.

It is evident that the transient response curves for output current, shown in Figure 6, are not in general of exponential form. Therefore the practice, which has become rather common, of describing magnetic amplifier transients in terms of the time for the change to reach 63 per cent of completion, by analogy with a linear case, may not be justified.

Experimental Checks

The results of the analysis given here have been checked thoroughly by experiment. The experiments to be described were done with the hypernik cores used in earlier work[1,3,4] but extensive measurements also were made using a pair of conventional 1.5 kva single-phase power transformers connected as magnetic amplifiers in accordance with Figures 1 and 3, and the agreement with the analytical results was equally satisfactory.

Two typical oscillograms obtained with a direct-inking type instrument are shown in Figure 7. The upper trace in each case is the control current and the lower, the load current. Since it often was extremely difficult to determine the starting point of the transient, a small auxiliary circuit was used to give a pip on the control current trace at the instant of closing the switch.

The upper record of Figure 7 is for an amplifier with series-connected output coils, Figure 1, and the lower for one with the parallel connection, Figure 3. The core material is that for which Figure 2 is drawn.

In both cases $N_1I_{1_\infty} = 120$ ampere-turns, $R_1 = 98.5$ ohms, $R_2 = 109$ ohms, $N_1 = N_2 = 2{,}000$ turns, $B_m = 45.7$ kilolines per square inch and $B_0 = 43.2$ kilolines per square inch resulting in $uB_{0_\infty} = 2.66$. The factors τ_s and τ_p are calculated to be respectively 0.0715 and 0.137 second. The supply frequency is 60 cycles. The slower response of the parallel case as predicted, and the initial jump in control current in this case are evident. Figure 8, for the same cases as Figure 7, shows the transient envelope of output current plotted against time in dimensionless form as in Figure 6. It satisfactorily confirms both the predicted form of the transient and the predicted relation between the series and parallel cases.

Figure 9 shows additional calculated and measured envelopes of the output current transient for a series connection with time plotted in seconds instead of in dimensionless form. The experimental conditions are as before, except that $B_m = 22.9$ kilolines per square inch, the control voltage for the middle curve is the same as for Figure 7. The upper and lower curves were obtained respectively with doubled and halved control voltage, the control circuit resistance remaining unchanged throughout. B_{0_∞} is 68.1, 56.8, and 45.5 kilolines per square inch when $N_1I_{1_\infty}$ is 240, 120, and 60 ampere turns respectively as per equation 14.

Finally Figure 10 reproduces the middle curve of Figure 9 and an additional curve (calculated and experimental) obtained by doubling both the control circuit resistance and control voltage. Thus the influence of control resistance on the time scale for unchanged values of B_m and B_{0_∞} is evidenced.

Effects of Load and Frequency

The transient response curves of Figure 6 are derived for the case of zero load impedance. For loaded amplifiers in the steady state it is conventional, as has been noted,[4] to investigate the performance using for the voltage E_m across the amplifier the vector difference between the supply voltage and the load voltage drop ignoring harmonics. The same procedure can be applied in the transient case obtaining B_m from the value of E_m corresponding to the final steady state. Actually higher values of voltages than this will exist across the load coils before the output current reaches its steady state, and the actual build-up of the output current may be expected to be somewhat faster than calculated using the final steady state B_m in the formulas developed for the no-load case. A more accurate analysis of the loaded amplifier obtainable by cutting the transient into intervals suggests itself.

From the analysis it appears that the influence of the supply frequency upon the response of the amplifier can be discussed only when the conditions for comparison are specified clearly in terms of the true independent variables B_m, E_{dc}, and R_1. If supply voltage and frequency are varied at the same rate, B_m does not change in the amplifier without load and therefore uB_{0_∞} does not vary and the response time in seconds remains unchanged. A readjustment of voltage and frequency for a loaded amplifier will generally also involve rematching of the load. Suppose specifically that a-c supply voltage and frequency are doubled and that the load resistance also is doubled, then the transient response is not affected, while of course the gain resulting will be doubled.

It is conceivable then to increase R_1 and E_{dc} thus improving the transient response at the expense of gain. For instance, if R_1 and E_{dc} then also are doubled the gain will be brought back to the value at the original frequency while the factor τ_s will be cut to one-half and the build-up transient for the series-connected amplifier will be twice as fast. General statements to the effect that transient durations should be measured in cycles of the supply frequencies rather than in seconds probably imply that changes of frequency are actually accompanied by changes in load, supply voltage, control circuit voltage, and control circuit resistance, as indicated before, and that

Figure 9. Envelopes of output current transients for a series-connected magnetic amplifier

The curves are calculated; the points are measured

Figure 10. Envelopes of output current transients for a series-connected magnetic amplifier showing the effect of control circuit resistance

The curves are calculated; the points are measured

higher gains inherent to higher frequencies are being entirely sacrificed for higher speed of response. In any event these considerations apply, as stated initially, in the range of frequency in which eddy currents may be neglected.

Conclusions

The foregoing analysis is based on the approximation that during the transient, the values of the direct component of core flux density (B_{0i}) are obtained in terms of the crest of the a-c voltage across the amplifier and of the direct component of control current by use of the same expression which has been derived in reference 4 for steady-state operation. This approximation, suggested from the results of a number of step-by-step computations, allows development of a theory which yields results checking with experiments for materials whose normal magnetization curves can be reasonably fitted with a hyperbolic sine function and for transients which, as commonly happens, persist for at least several cycles of the applied alternating voltage.

Formulas and curves are obtained which express the build-up of the a-c envelopes for series-connected and parallel-connected 2-core amplifiers without feedback. Influence of core material, control voltage, and design data is embodied in a time factor. Effects of load and influence of supply frequency are discussed.

The Alco-GE 4,500-Horsepower Gas-Turbine Electric Locomotive

A. H. MOREY
NONMEMBER AIEE

BASIC design features of this locomotive were dictated by current railroad needs. The keynote is simplicity, as far as this is compatible with the application of a new type of prime mover to railroad motive power. The result has been a unit with control and characteristics essentially the same as those of the modern diesel-electric locomotive, except where power-plant characteristics required or permitted advantageous differences.

General Design

The Alco-GE gas-turbine electric locomotive, shown in Figure 1, is designed for freight service. It is an 8-axle 8-motor B-B-B-B locomotive, weighing 253 tons (average) and rated at 4,500 horsepower for traction (at 80 degrees Fahrenheit and 1,500-feet elevation). The locomotive is 83-feet $7^1/_2$-inches long, and 14-feet 3-inches high over the roof sheets. It will negotiate curves of 288-feet radius.

This locomotive is designed to burn grade 6 fuel oil with some restrictions. Its specific fuel consumption is relatively high compared to diesel-electric locomotives, and low compared to oil-burning steam locomotives.

The general design, especially the power rating and weight of the locomotive, was developed from analyses of freight and passenger locomotives in use in this country in 1941 and 1946. These analyses indicated that about 75 per cent of the freight locomotives were in the 4,000- to 5,000-horsepower range and had approximately 500,000 pounds on drivers. The studies also showed that approximately 90 per cent of the total locomotives in use in road service handled freight. Consequently, it was decided to concentrate on designing a freight locomotive in this range of power and weight. To be attractive and profitable to the railroads, this locomotive must show a low initial investment, low fuel cost, and low maintenance cost.

Mechanical Construction

The mechanical construction of the locomotive is somewhat unconventional. Instead of the usual truss work in the sides of the locomotive cab, the equivalent mechanical structure is built into the cab underframe. The superstructure, including the roof, hatch covers, side walls, and so forth, is supported on vertical uprights from this main underframe in what we have called an "umbrella type" construction. This is illustrated in Figure 2. This design was developed because of the necessity for carrying relatively large amounts of fuel and for keeping this fuel below the level of the power plant and generating equipment. In order to obtain an adequate "cruising range," it was necessary to provide fuel oil in proportion to the horsepower rating of the power plant. For the present locomotive, this requires storage space for approximately 6,500 gallons of fuel. Such a quantity is much larger than can be carried in a conventional manner between the trucks. Consequently, the fuel storage tanks are built into the main underframe structure of the cab.

The trucks are of the conventional 2-axle swing-bolster type, as indicated in Figure 3. Each pair of trucks is connected by a span bolster which, in addition to spanning the two trucks and supporting the locomotive cab, also acts as a traction-motor air duct. This arrangement gives a high degree of flexibility on curves. It also has sufficient vertical flexibility to give satisfactory riding qualities even on comparatively rough track. Resonant vibration between the truck equalizers and the swing bolsters was encountered at low speeds. Damping means were provided in the spring system and no further trouble has been encountered.

Power Plant

The power plant, Figure 4, is the simplest type of gas-turbine power plant having the compressor and turbine rotors essentially on the same shaft. It is of the "straight-through" type of construction. Air entering the inlet at the left goes through the compressor, where the pressure is raised to approximately five atmospheres gauge. It then enters the combustion chambers where fuel is admitted and burned. The products of combustion pass through the two turbine stages where

Figure 2. Side view and cross sections of locomotive cab showing "umbrella type" construction

the available energy is transformed into mechanical energy, and through the exhaust ducts to the roof discharge. No heat exchangers or intercoolers are used. The power-plant governor, fuel pumps, and so forth, are mechanically driven from the shaft extension on the inlet end. The power output is taken off through a shaft extension on the exhaust end of the machine.

Electric Equipment

The electric transmission consists of four d-c traction generators driven by the power plant through a reduction gear. This power is absorbed in eight traction motors, each pair of traction motors being connected to a single generator with no electrical interconnections. Auxiliary power is furnished by a d-c generator driven directly from one of the traction generators. This supplies the necessary power for the auxiliaries which are used in starting. The balance of the auxiliary power is furnished by an alternator direct connected to another of the traction generators. Such auxiliaries as traction-motor blowers, water circulating pumps, cooling fans, amplidyne exciters, and so forth, receive power from this source.

The power plant is started by a diesel engine-driven generator set. This generator is connected across one of the traction generators serving as a motor to crank the power plant up to the firing speed and to assist in further acceleration to a speed where the power plant is self-supporting.

Necessary fuel heating and cab heating is accomplished by a vapor car-heating boiler. The heating system and boiler are operated on a closed cycle so that storage space need be provided only for the necessary makeup water.

Apparatus Location

The relative location of various pieces of apparatus is shown in Figure 5. The nose compartments of the locomotive are taken up with train control and air brake equipment. The operating cabs are quite conventional and follow closely the pattern set by the diesel-electric locomotives. Necessary transmission and auxiliary control are located in the two control cabinets just back of the operating cab at each end. The diesel-engine with its generator and the heating boiler are shown adjacent to the right control cabinet. Following these, to the left, is the train air compressor and above it the radiators for cooling the lubricating oil. In the center is shown the gear unit with its four traction generators, the two auxiliary generators, and a connection through the alternator for driving the train air compressor. At the left in the equipment cab is the main power plant and the second control cabinet.

Figure 6 shows a typical cross section through the locomotive. It is of interest in that it shows the location of the main fuel tank, air inlet louvers and, particularly, the bus bars and control wiring above the aisles. All piping is located beneath the aisle floors or beneath the main fuel tank. This calls for a rather unusual treatment of the sand boxes since they must be below the bus bar and control wiring locations.

This location of the electric connections was designed to keep them dry. It has proved quite effective even though snow and water are drawn through the air inlet louvers into the cab. It also is quite effective in keeping cleaning compounds that may be used in the locomotive from coming into direct contact with the wiring and deteriorating the insulation.

Control

The control requirements on this locomotive are essentially the same as the requirements for any internally-powered locomotive. The control, at least from the engineman's point of view, must be simple. It must give adequate control of tractive effort for safe and satisfactory train handling. It also must provide the necessary safeguards against such things as: locomotive overspeed, low or high lubricating oil pressure, overspeed, or excessive temperature on equipment.

Automatic motor transition and field shunting, operating as a function of locomotive speed, are provided. The dynamic braking control is the same as that used on diesel-electric locomotives, with the energy dissipated in resistors. In short, since the diesel-electric locomotive has become the standard of com-

Figure 3. Running gear showing span bolster and two swivel trucks

Figure 4. Longitudinal section of gas turbine

parison for new motive power, the same pattern of control was followed. Full details of the control will be covered by other papers.[1,2]

This locomotive is handled in essentially the same manner as the diesel-electric. It differs in only one feature, namely, the rate at which the controller can be advanced from notch to notch. This is lower than the rate on the diesel-electric locomotive. The power plant, with its connected load, has considerably more inertia than the diesel-electric power plants on present-day locomotives. Consequently, its rate of acceleration is lower.

A notching guide is provided on the instrument panel at the engineman's position to aid in advancing the controller on this locomotive at a proper rate. This guide will indicate, at a glance, whether the engineman is moving the controller handle too rapidly. Although the proper rate is lower than that to which the enginemen are accustomed, no difficulty has been experienced in starting or handling trains. The reapplication of power after shutoffs proved to be too slow for starting trains. A switch has been installed on the instrument panel which will hold the power plant at full speed under these conditions and permit rapid reapplication.

Locomotive Characteristics

The locomotive characteristics are, of course, the characteristics of any internally-powered electrically-propelled locomotive as far as speed and tractive effort are concerned. The capacity of this type of power plant varies with changes in ambient temperature and elevation.

The engineman, however, only sees a change in the power which he can obtain from the electric locomotive.

Locomotive control permits full utilization of available power, up to maximum capacity of the drive, line *E*, Figure 7. Somewhat unconventional speed-tractive effort characteristics result, as shown in Figure 8.

The dotted line of Figure 8 denotes the constant horsepower characteristic, line *D* of Figure 7, while the solid line of Figure 8 corresponds to maximum power conditions, line *E*, Figure 7. Speed-tractive effort characteristics in the cross-hatched area between the dotted and solid lines in Figure 8 will be realized when the locomotive is operating under the conditions corresponding to the cross-hatched section of Figure 7. These areas represent extra power available due to the particular characteristics of the gas turbine.

Installing power-plant capacity to fully utilize all of the capacity in the electric drive is entirely a question of

Figure 5. Layout of apparatus in locomotive cab

Figure 6 (left). Cross section of locomotive cab showing location of electric wiring and piping

Figure 7 (right). Chart of typical gas-turbine electric drive performance

economics. In the case of the gas-turbine power plant with its low specific weight and space characteristics and its fairly wide variation in output with altitude and ambient temperature, it appears to be good business to make this power available in the form of tractive effort whenever the power plant is capable of developing it. This is especially true since the restriction of the output to the conventional constant horsepower would entail the operation of the power plant at partial loads, with consequent poorer efficiency, over a fairly large percentage of its normal life.

Control System for a 4,500-Horsepower Gas-Turbine Electric Locomotive

T. J. WARRICK
ASSOCIATE AIEE

Synopsis: This paper is concerned with the control equipment of the 4,500-horsepower Alco-GE gas-turbine electric locomotive. It includes a description of the control apparatus and functions, and outlines problems encountered in its application. Control systems relative to this new type of prime mover are dealt with in particular.

Basic Considerations

THE main objective of the gas-turbine electric locomotive development program is the evaluation of the gas-turbine power plant as a prime mover for locomotive use. On this basis, new developments were limited to those peculiar to this type of power plant application. Wherever possible, control equipment comparable to that employed on diesel-electric road locomotives was used.[1] When chosen, this equipment represented the best possible in design, and it has since proved reliable and successful. Further benefits derived from applying this standard equipment are lower first cost and simplification of the maintenance, servicing, and renewal parts problems.

Previous articles have been published on design and testing of the gas turbine power plant.[2,3] Two additional papers are being presented at this session.[4,5] One concerns the construction, design, and operation of the locomotive; while the other deals with the rotating electric apparatus.

Paper 50-78, recommended by the AIEE Land Transportation Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30-February 3, 1950. Manuscript submitted October 26, 1949; made available for printing December 5, 1949.

Propulsion Control

For maximum hauling power in freight service, all eight locomotive axles are driven by series-wound d-c traction motors. Two motors are powered from each of the four main generators and each system is electrically independent of the others during motoring. Conventional series and parallel connections are used with a single step of field shunting in the parallel connection. Referring to Figure 1, the "hole" in the speed tractive effort curve at the transition point from series to parallel connection of the motors is small enough that field shunting in the series connection is not warranted.

Automatic transition, operating as a function of locomotive speed, is provided from series to parallel, and from parallel full field to parallel shunted field. Referring again to Figure 1 and extending the series and parallel curves at their intersection, it can be seen that for optimum locomotive performance the transfer from series to parallel should occur at 19 miles per hour. The fact that the transfer is automatic relieves the engineman from the responsibility of initiating it at the proper speed, and assures that both forward and backward transitions will be correctly made. This results in less shock to the train and the electric equipment of the locomotive. Supervisory control is not provided. Smoother forward transition is obtained by transferring four motors at a time. The first four, after completing the cycle, transfer the remaining two generators and their motors. The controls are such that even though one generator is cut out, its associated generator and its motors will transfer. Backward transition is not staggered.

See Figure 2 for motor connections.

Relays in each generator circuit provide ground protection for power and equipment circuits. Disconnects are not provided. In case of fault, one generator and its associated pair of motors are cut out. However, the operation of three generators and their motors continues. These ground relays can be operated manually to cut out any generator, thereby eliminating the need for separate traction motor cutouts.

Controls identical to those on diesel-electric road locomotives are used for dynamic braking. On this locomotive, however, twice the equipment is necessary since eight motors are used instead of four. Two generators are used to excite the traction motor fields during dynamic braking. Four identical braking resistors are necessary to dissipate the power developed by the traction motors.

Figure 3 shows the power connection diagram for half of the locomotive during braking. The four traction motor exciting fields are tied in series across generator 2. Each pair of motors is connected to one braking resistor and, in effect, becomes a pair of separately excited generators. By varying the output of the exciting generator in much the same manner as during motoring, the amount of braking effort is controlled. Figure 4 illustrates the speed-braking effort curve.

The excitation scheme is quite similar to that currently employed on diesel-electric road locomotives.[6] The main difference lies in the current limit portion of the control. On diesel-electrics the excitation system provides for limiting generator line and field currents to safe values at the high-current and high-voltage ends of the characteristic curve, respectively. Since a diesel engine is essentially a constant horsepower machine at any particular speed, the load control rheostat on the governor is depended upon to limit maximum generator output. This scheme is not suitable for a gas turbine since its power output varies, depending upon the altitude and ambient temperature at which it is operating. It is not practical to design generators and motors to absorb all the available power that the turbine is capable of delivering under ideal conditions. A field-current-biased line current scheme was developed to replace the straight line current feature of the diesel-electric scheme. This, in effect, limits the line current at the high-current end of the characteristic curve and also limits the power at the maximum power portion of the curve, as shown in Figure 5.

Control of power plant speed and generator power demand (locomotive power) is provided in 20 steps on the controller. This number of throttle notches was selected, instead of the customary eight, to give finer and better control of tractive effort as well as better locomotive performance when working near limiting adhesion. The throttle handle operates a potentiometer which feeds a d-c signal into the excitation system of all four generators. By the proper selection of taps on the potentiometer, equal increments of tractive effort are obtained. The engineman is prevented from advancing the throttle handle too fast (and consequently making too rapid an increase in power plant speed and output demand) by an "automotoneer." This feature is a mechanical lock on each throttle notch position which prevents the handle from being advanced more than one notch at a time. To advance another notch it is necessary to retard the throttle handle a half notch and then advance to the next position.

To obtain optimum locomotive performance and to have better control of tractive effort, a notching guide in the form of a voltmeter is installed beside the ammeter on the engineman's panel, see Figure 8. This meter is connected across the stabilizing potentiometer of the fuel regulator and, by the colored band scale markings, indicates the availability of power-plant output. The two main divisions of the meter show whether the power plant is operating in either fuel control or load control. When in fuel control, the power plant is capable of developing more output than the load is demanding; but when in load control any further called-for increase in load demand will be nullified by governor action. By watching the amount of generator load reduction, the engineman can govern the rate at which he advances the throttle handle to call for more tractive effort.

By means of a switch, located at the engineman's panel, the power plant can be accelerated to, or held at, full speed without power being delivered to the traction motors. With this arrangement, the throttle handle may be manipulated so as to secure the desired tractive effort more rapidly and with better control than if part of the power output of the turbine is diverted to accelerating the power plant.

New Control Problems

The application of a gas-turbine power plant as a locomotive prime mover necessitated the development of some new control systems and equipment, and the solution of problems not encountered heretofore. The new major control functions may be grouped as follows:

1. Power plant control.
2. Power plant cranking and cooldown.
3. Generator power limit.

Some of the new components developed for these applications were: a power plant regulator incorporating an electric positioning motor, a magnetic amplifier for controlling this positioning motor, a flame detector system, a voltage regulator for the 400-cycle power supply, an excitation system incorporating a power limit separate from that of the governor, and new control schemes for turbine cranking and cooldown.

Power Plant Regulator (Governor)

The power plant regulator is shown in Figure 6. The functions of the regulating system are: to control load and power plant speed; to protect the turbine from excessive exhaust temperatures and overloads; to recognize the ability of the

Figure 4. Speed braking-effort curve for a 4,500-horsepower gas-turbine electric locomotive

power plant; and to provide remote operation during firing and running.

The basic speed control circuit is similar to that used on many diesel-electric locomotives.[7] Part of it consists of a 3-phase tachometer-generator driven directly from the power plant with its output rectified, giving a d-c voltage proportional to turbine speed. This d-c signal, in turn, energizes a spring-loaded solenoid which operates the pilot valve of the speed servo. This determines the amount of fuel being delivered to the power plant by hydraulically controlling the position of the wobble plate which changes the effective stroke of a 6-port pump driven by the power plant. Power plant speed is determined by the circuit resistance and is proportional to it since a constant current of 0.475 ampere is required to balance the system.

In order to prevent undue thermal shock it is necessary to limit the rate of change of temperature in the turbine. For this reason temperature measuring equipment, consisting of a gas-filled bellows located in the exhaust chamber, forms an essential part of the governor system. The rate of temperature change is controlled by a rate piston which restricts the rise to 20 degrees per second after an initial instantaneous jump of 200 degrees Fahrenheit. A mechanical stop is used to limit the maximum temperature.

Further control of the rate of temperature change is obtained by an electric positioning motor, located within the fuel regulator. This motor is mechanically geared to the speed-setting rheostat, so that its position determines power plant speed. The thermal shock which would result from an instantaneous change in speed (and hence in fuel rate) is lessened by limiting the speed of this motor. In the event of too rapid a change or too high an exhaust temperature, the temperature measuring equipment can reduce the fuel rate called for by the speed control circuit.

During normal running, the positioning motor receives its signal from the voltage taken off a potentiometer operated by the throttle handle. During firing this signal is received from a master rheostat governed by the turbine control switch. Rectified 400-cycle power controlled by a magnetic amplifier is used to drive this motor. The voltage at the brush arm of the follow-up rheostat, which is gear-driven by the positioning motor, signals the position of the motor. This brush arm is electrically connected, through the windings of two saturable reactors, to the brush arm of whichever potentiometer is controlling speed. With both voltages equal no current flows and the reactors are balanced. When the called-for speed-voltage is different from that of the follow-up rheostat, current flows through the reactors causing an unbalance in the system. Depending on the direction of current flow, power is supplied to the proper field of a split-pole series d-c motor

Figure 6. Power plant fuel regulator

causing it to rotate until the system is again balanced.

Under certain conditions, it is necessary to further control the load demand of the traction generators. The feature of the governor which provides for this is similar to the one used on many diesel-electric road locomotives. With the power plant loaded and the fuel regulator allowing maximum fuel rate (permitted by the aforementioned limits) the speed control portions of the regulator can overtravel and regulate the speed by the control of the generators' output through a load control rheostat. When this overtravel takes place it, in effect, commutates resistance in the current-controlling reactor of the excitation system to reduce the field excitation and hence load demand of all four traction generators.

Power and Speed Scheduling

The large power required for acceleration, the characteristics of this type of power plant, and certain economic considerations made it desirable to incorporate a variable speed schedule into the power plant speed control circuit. A rheostat in the high side of the potentiometer circuit provides this variable speed program. The idle speed range is between 60 and 100 per cent of full speed (6,900 rpm).

When the power plant speed is below the called-for speed, the governor reduces the power demand of the generators through the medium of the aforementioned load control rheostat, making more power available for acceleration. Greater acceleration could be obtained by reducing the power plant output to zero, but then the locomotive would be subjected to sudden shocks of varying power. A compromise is reached by providing 40 per cent reduction in the generator power demand. It also is possible to vary the speed change per notch by the use of a nonlinear potentiometer. By having the lower notches produce greater speed

Figure 5. Traction generator characteristic curves for a 4,500-horsepower gas-turbine electric locomotive

changes, better locomotive performance is obtained.

Flame Detector

The function of the flame detector is to hold the fuel valve open as long as fire is sustained in the combustion chambers. The flame detector system includes two sets of thermopiles located in two of the combustion chambers. The d-c signals produced by them are separately amplified and, with their outputs paralleled, either can energize a standard control relay to maintain fuel flow to the nozzles. The amplifiers are of the magnetic type with two stages of amplification.

Several problems were encountered in the design of this system. It must be fast enough to detect the presence or absence of fire in the combustion chambers before an excessive amount of fuel can be injected, with consequent damage resulting from high temperature when ignition does take place. To meet these conditions a rugged, yet small-time-lag thermopile was built and so located in the combustion chamber that it is not directly in contact with the fire. Cooling air is directed so as to provide the cold junction within the element as well as the necessary general cooling.

In order to obtain satisfactory amplification, a constant a-c voltage supply was needed. Since 400-cycle power was already available, it was only necessary to provide better voltage regulation. A magnetic-type regulator was developed for this purpose which consists fundamentally of a single-stage amplifier and a reference and voltage build-up circuit.

Auxiliary System

There are two separate electric auxiliary power systems on this locomotive.

1. The d-c system comprises those auxiliaries which must function when the power plant is shut down. A 32-cell battery charged from either one of two identical auxiliary generators furnishes stand-by power. One generator is driven by the turbine and the other by a diesel engine which is not in use during normal turbine operation. The power plant starting fuel pump, fuel heat boiler, locomotive lighting, power plant cranking control, 400-cycle motor-alternator set, and the lubricating and water booster pump motors are all required previous to and during power plant starting, and hence are d-c powdered.

The high inertia of the power plant and its connected load, and the time required to crank it to self-sustaining speeds,

Figure 7. Turbine control panel

(above) with covers
(below) without covers

necessitate a large power supply. Weight and space limitations prohibited the use of batteries as the source of supply, hence an auxiliary diesel-driven generator set is employed. The diesel engine is rated 210 horsepower at 2,100 rpm and its generator is capable of delivering 140 kw at this speed. Both turbine-driven and diesel-driven generators are rated 50 kw for battery charging.

2. The a-c system comprises those auxiliaries which function only when the power plant is operating. A 3-phase 80-cycle 290-volt alternator, driven from the main power plant, provides for operating the following pieces of induction-motor-driven apparatus: four amplidyne exciters, four traction motor blowers, two radiator fans, and the coolant, lubricating, and fuel pumps. Most of these motors are permanently connected to the alternator through circuit breakers. The radiator fan and coolant pump motors are connected through separate contactors (with overloads) which are controlled as a function of lubricating oil temperature.

Power Plant Cranking and Cooldown

Power plant cranking and diesel control are practically automatic. A 3-position diesel control switch and a five-position turbine control switch are located on the turbine control panel, Figure 7. This, along with the d-c circuit breaker panel, is mounted at the side of the power plant. The positions of the diesel control switch are *OFF—RUN—CRANK*, and those of the turbine control switch are *OFF—CRANK OR COOLDOWN—FIRE AND IDLE—BUNKER "C"—RUN.*

Diesel Starting. Before starting the diesel engine, the water booster pump must be started by closing its circuit breaker and the diesel and turbine-start circuit breaker must be closed. The control switch is moved to the *RUN* position. This allows the throttle operator on the diesel to advance to idle speed setting. An electric positioning motor drives the speed adjusting shaft of a conventional hydraulic speed-droop governor at proper limited speed. Cam-operated contacts on the throttle operator are used to control the position of the motor. When ready to crank, the diesel control switch is moved to the *CRANK* position and held there. The generator, acting as a series motor powered from the battery, cranks the engine. As soon as the diesel fires, the switch is released and springs back to the *RUN* position. In this position the diesel-driven generator is automatically regulated at 75 volts and is connected to the d-c auxiliary bus for battery charging and supplying the auxiliary load.

Power Plant Cranking. Previous to starting the power plant the grade 6 fuel oil is heated to approximately 200 degrees Fahrenheit by the fuel-heating steam generator.

The diesel-driven generator is connected to one of the main traction generators for power plant cranking. A conventional self-separate excitation scheme is employed on the diesel generator, while the traction generator is battery-excited. Since the battery must furnish the d-c auxiliary power required during cranking and firing, it is necessary to limit the number and length of starts allowed before additional charging is required.

With the proper circuit breakers closed, power plant cranking is initiated by moving the turbine control switch to the *CRANK* position. The diesel engine accelerates to a predetermined speed, simultaneously accelerating the power plant. The control switch now may be moved to the *FIRE AND IDLE* position,

Figure 8. Engineman's position, showing controls and instruments

but fuel injection and ignition will not take place until the minimum speed relay operates at 10 per cent of power plant speed. This relay measures speed indirectly from the rectified output of the turbine-driven tachometer-generator. If the fuel does not ignite within 45 seconds, the fuel valve is automatically closed and ignition shut off.

A time-delay relay prevents repetition of the firing cycle for a period of four minutes to allow sufficient time for purging fuel from the combustion chambers. In case of a mis-fire it is necessary to move the turbine control switch to the *CRANK* position and, after the required time delay, back again for firing. When firing occurs, the flame-detector relay operates and causes the diesel engine to accelerate to full speed. After firing, a relay introduces a 90-second time delay before the fuel rate of the power plant is increased, thereby allowing the exhaust temperature bellows to become operative. As the power plant approaches idling speed a reverse-current relay automatically uncouples the diesel-driven generator from the main traction generator, and the diesel engine returns to idling speed for battery charging. The diesel engine may be shut down and the turbine-driven auxiliary generator used for battery charging by moving the diesel control switch to the *OFF* position. The same voltage regulator, overload relay, and reverse current relay control both the diesel- and the turbine-driven auxiliary generators.

Grade 3 fuel oil is used during firing. The transfer to grade 6 is, at present, a manual operation. As soon as the transfer is complete, the locomotive is ready for service.

Approximately four minutes are required to crank, fire, and accelerate the unit to idle speed. The control of the locomotion of the gas turbine-electric locomotive is quite similar to that of a diesel-electric road locomotive, as indicated by Figure 8.

Power Plant Cooldown. Normally, at shutdown the power plant is cranked at low speeds for 15 to 20 minutes. Low power is required for this cranking and hence the diesel engine is operated at idling speed. It also furnishes power for battery charging during this cooldown period.

Hostler Operation

A means has been provided for moving the light locomotive around yards and terminals without starting the main power plant, by a simple commutation of control circuits. For such movements the diesel engine is started in the normal fashion and the hostler control switch is turned to the *ON* position. This connects the diesel-engine driven generator to two of the traction motors in series. The same self-separate excitation arrangement is used for hostler operation as for power plant cranking. Since the diesel-driven generator cannot be used for battery charging during hostling, the length of time allowable for such movements depends on the condition of the battery and what d-c auxiliaries are being operated.

The hostler controls the tractive effort with the throttle lever indirectly by varying diesel engine speed. Notch 1 produces tractive effort with the diesel engine at idling speed; Notch 2 holds the speed at which the diesel engine is operated; Notches from 3 onward cause the diesel throttle operator to advance steadily to obtain diesel speeds between idle and full. On level track the locomotive will attain a speed of about 12 miles per hour.

Protective Equipment

Six emergency stop switches, one at each engineman's stand and the rest in the engine room, provide means of shutting down the turbine, fuel heat boiler, diesel engine, and starting fuel pump.

No fuses are used, but all electric circuits and equipment are fed through circuit breakers for protection. All the a-c, and most of the d-c circuit breakers are for protection only and are normally left closed. The d-c circuit breakers controlling the lubricating oil pump, the 400-cycle set, the water booster pump, the starting fuel pump, and the diesel and power plant start circuit breaker are used both for protection and as switches.

Both the power plant and the diesel engine are protected against overspeed. The overspeed switch on the diesel engine is part of the governor and mechanically trips the fuel valve. On the power plant, the contacts open to de-energize the turbine stop relay, thereby shutting off fuel and also by-passing the control oil so that the pump goes to zero stroke.

A manually reset, overload relay in the common negative circuit of the diesel and turbine-driven auxiliary generators provides overload protection for both machines. If the overload trips, field is removed from both generators and the line contactors are de-energized.

Temperature and pressure switches protect the power plant and main reduc-

tion-gear unit in case of low-lubricating oil pressure and high-lubricating oil temperature. The turbine is protected against too high an exhaust temperature by a bellows-operated shutdown switch.

The d-c lubricating oil pump motor is powdered through a contactor which operates as a function of lubricating oil pressure. In cranking the power plant the d-c pump furnishes lubricating oil. As the a-c pump increases in speed, their combined output increases until an oil pressure switch operates and shuts down the d-c pump. In case the a-c pump fails for any reason, and the oil pressure drops, the d-c pump will automatically start before any damage is done to the bearings.

Summary of Tests to Date

Preliminary testing of this locomotive has indicated that the control equipment is basically sound. There have been no troubles encountered to date with the well-seasoned standard equipment used. Little difficulty has been experienced with the new equipment developed specifically for this application. Future testing may result in minor alterations of control equipment; however, no basic changes in the over-all control structures are contemplated.

Rotating Electric Equipment for a Gas-Turbine Electric Locomotive

O. C. COHO
ASSOCIATE AIEE

Synopsis: A new type of prime mover, in the form of a gas-turbine power plant, recently has been successfully applied in a locomotive. The problems encountered and the electric equipment employed are, in many respects, similar to those of diesel-electric locomotives. This presentation deals primarily with those features, as regards this locomotive application, that it is felt are sufficiently unique to be of general interest.

Electrical Drive

THE BASIC problem in the application of electrical drive is that of converting the prime-mover power available in the form of torque at high rotative speed to tractive effort at the driving wheels over the range of locomotive operating speed. It is desired to make the full prime-mover power available as tractive effort, from the minimum locomotive speed at which point the wheels will slip, to the maximum full-power speed. The latter is usually a high fraction of the maximum permissible locomotive speed as dictated by other considerations. At low locomotive speeds, the prime-mover power appears as high tractive effort whereas, at high speeds, the tractive effort decreases essentially in inverse proportion to the locomotive speed. The system is thus basically a torque converter of infinitely variable ratio within the rating capabilities of the equipment.

In the design of such an electrical drive system, cognizance is taken of the fact that below a certain locomotive speed, full-power application is generally of limited duration, such as in starting a train or ascending a grade. Advantage is taken of this fact to utilize the short-time torque overload capacity of electric apparatus, thus resulting in smaller, lighter equipment than would be required if continuous operation in the low-speed range were provided.

The foregoing is merely a brief review of the electrical drive in general. The remarks are equally applicable for any system with a constant-speed, constant-torque prime mover.

Gas-Turbine Prime Mover

The type of gas turbine selected for this application is essentially a constant-speed, constant-torque power plant at full power and, in this sense, is comparable to the diesel engine. Its nominal rating is 4,800 horsepower, of which 4,500 horsepower is allocated for traction and 300 horsepower for auxiliaries. This rating is stipulated at 80-degree Fahrenheit ambient and 1,500-foot elevation. However, the turbine power available is a function of both ambient air temperature and pressure (altitude). At low temperatures and elevations, the power capabilities of the turbine are somewhat higher than at high temperatures and/or altitudes.

Thus the first problem encountered in this application was that of selecting the rating point about which the design of the electric propulsion equipment should be centered. To provide equipment suitable for transmitting the maximum available power-plant output over the entire range of locomotive speed would mean carrying much extra and expensive equipment weight on the locomotive when ambient conditions were such that this peak power was not available. Accordingly, the electric transmission was chosen finally to handle 4,500 horsepower for traction over essentially the entire speed range.

Locomotive Performance

The full-power performance of the locomotive is illustrated in Figure 1, which shows the relationship of tractive effort and speed. One of the curves represents the locomotive characteristic at the nominal 4,500-horsepower rating, and the other the limiting characteristic permitted by the electrical drive when more than nominal power is available from the power plant. The equipment is designed for a maximum tractive effort of 150,000 pounds. This is dictated by wheel slip based on 30 per cent adhesion. The maximum speed, 69 miles per hour, is determined by the limiting speed of the traction motors. The tractive effort at the continuous rating of the traction motors is 77,800 pounds at 18 miles per hour.

This performance characteristic is obtained through the use of eight traction motors receiving their power from four traction generators geared to the gas-turbine power-plant shaft. Each generator independently furnishes power to two traction motors. From standstill to 19 miles per hour, the two traction motors are connected in series across the generators, and from 19 to 69 miles per hour, they are connected in parallel. At 38 miles per hour, the motor series fields are shunted to extend the speed range over which full power can be handled.

Traction Generators

Considerable thought was given to the arrangement and design of the traction-generating equipment. Inasmuch as the full power-plant speed is 6,700 rpm, gearing is necessary to reduce the speed to a value which can be handled by traction generators built within current design practice. Various studies were made as

Paper 50-79, recommended by the AIEE Land Transportation Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted October 24, 1949; made available for printing December 6, 1949.

O. C. Coho is with the General Electric Company, Erie, Pa.

Figure 1 (left). Speed-tractive-effort curve showing full-power performance

Figure 3 (right). Schematized section of generator gear-unit assembly

to the best arrangement of the equipment centered around such a reduction gear unit.

While the power is too great to be handled by a single commutator machine of a diameter that will readily fit in the locomotive, it is possible to design a generating unit having two armatures. Such a pair of generators, however, could not be assembled with the gear reduction set as a self-contained unit. This would involve individual installation of the components within the locomotive and connection through a parallel misalignment type of flexible coupling. Additional study showed that this solution had no advantage in weight and was possibly at a disadvantage from the cost and space standpoint. The 3-generator layout was eliminated for similar reasons plus the fact that it is quite awkward to match the output of three generators to eight traction motors. The design was ultimately resolved into a single self-contained generating unit consisting of a gear box with four overhung, close-coupled generators. The gearing consists of a single 6,700-rpm double helical pinion driving two low-speed gears at 1,600 rpm. The pinion is driven by a splined shaft, so designed as to be readily removable in the event of interchange of equipment. The gears and pinion are supported and aligned within the box by their own bearings. Forced lubrication of the gears and bearings is obtained from the main lubricating oil system which also handles the power-plant bearing lubrication.

The four single-bearing generators are end-bell supported from the walls of the gear case. Each of the two low-speed gears drives two generators, one on each side, through steel disk-type flexible couplings. The gear bearings are designed to sustain not only the gear loading itself, but also the thrust and radial loads due to the weight and coupling of the generators. The over-all design is such that the generators may be mounted on the gear box on the assembly floor, and the complete assembly installed in the locomotive as a unit. Line-up within the locomotive, between the generating unit and the power plant, is then a relatively simple problem. Individual generators may be readily removed and replaced at any time after complete unit installation without disturbing the line-up of any other equipment.

The complete 4-generator gear unit weighs 38,000 pounds.

Figure 2 illustrates the general assembly details of the generators and gear unit. The high-speed power-plant shaft coupling passes between the two generators slightly above their centers. Scallops in the generator magnet frames to provide clearance with the shaft are evident in the picture. All frames are thus cut out on each side to provide a maximum of standardization and interchangeability. The generator frame has an outside diameter of $43^1/_2$ inches and an over-all length from bearing cap over coupling of 40 inches.

Further assembly details are illustrated by the cutaway plan view, Figure 3, where the rotating components of couplings, gearing, and one generator are shown in silhouette.

Each generator is nominally rated at 1,125-horsepower input for traction, consistent with the nominal power-plant rating, and in accordance with the AIEE standards for this type of equipment.

The generators are of the noncompensated type without pole-face windings. Each machine has six exciting poles and six commutating poles. They are conservatively designed, based on proved practice as regards mechanical and dielectric stresses, heating and ventilation, commutation, and performance limits.

Figure 4 illustrates the generator volt-

Figure 2 (below). Traction generator gear-unit assembly

Figure 4 (right). Generator characteristic curve for a 4,500-horsepower gas-turbine electric locomotive

Figure 5 (left). GE-752 traction motor

Figure 7 (right). Braking - resistor blower unit

ampere characteristic curve. The continuous rating of the generator is 1,125 horsepower, 1,600 rpm, 535 volts, 1,450 amperes. This figure shows also the limiting power curve to which the generators may be loaded when excess power is available from the power plant.

The generators are self-ventilated, each one being equipped with its own radial-discharge type fan located at the back of the generator as part of the steel-disk coupling assembly. Ventilating air is drawn from within the cab after it has passed through filters located in the side walls of the locomotive. The air enters the generators at the commutator end and then divides, part passing through the commutator risers and the armature core, and part passing over the surface of the armature and between the field coils. The air is discharged in chambers within the gear box and subsequently directed vertically out of the roof of the locomotive.

Comparison with Diesel-Electric Traction Generators

The generators are quite similar in general design and appearance to conventional diesel-driven generators designed for locomotive application. They embody many features inherent in the diesel-electrical units, such as short end windings, short commutators, and class *B* types of insulation. These features, plus the single antifriction bearing construction and end-bell mounting, result in a compact "pancake" design of relatively short length. This in itself is a significant item contributing to reduced locomotive length.

The generator field structure is somewhat simpler than a diesel-driven generator in that the conventional cranking winding is omitted. Although one of the generators serves as a cranking motor during turbine starting, separate shunt excitation is provided in this case. A further difference is found in the magnetic path design. In order to maintain good commutation at higher than normal rated horsepower, but within normal field and armature current limits, the magnetic structure is relatively heavier than that in the usual diesel-driven generator. This allows for the simultaneous existence of large exciting and commutating fluxes associated with such high horsepower, without the adverse effect of saturation on commutation.

Traction Motors

General Electric model *GE-752* traction motors, Figure 5, are provided. The locomotive has a total of eight motors, one on each axle. The motors are of the conventional force-ventilated 4-pole axle-hung series-wound type geared to the axle with single-reduction spur gearing. They are designed for heavy duty railway service and are a currently standard model in wide use on diesel-electric locomotives with similar axle loadings (62,500 pounds per axle). These motors heretofore have been rated at 900 amperes continuous for application at 500 horsepower with forced ventilation of 2,300 cubic feet per minute air flow. For the gas-turbine electrical application at 562.5 horsepower per motor, the core losses become of greater relative significance so that the continuous rating has been reduced to 875 amperes. Based on 74/18 gearing with 42-inch diameter wheels, this corresponds to a continuous tractive effort of 9,725 pounds per motor or 77,800 pounds total at 18 miles per hour. The motors are applied to transmit the full available horsepower over the speed range from 30 per cent adhesion at 8 miles per hour to 95 per cent of full speed or 66 miles per hour.

Figure 6. Speed-braking-effort curve for a 4,500-horsepower gas-turbine electric locomotive

Dynamic Braking

Since the locomotive has been designed particularly for use on freight applications, dynamic braking has been provided. This braking may be used independently or together with the train air brakes. The traction-motor armatures are loaded in pairs across fixed braking resistors while the separate excitation for the motor fields is furnished by two of the main generators. Braking control is obtained by varying the motor field excitation. The maximum braking rate is determined by motor armature and field heating as well as commutation limits. Between 19 and 58 miles per hour, 4,100 braking rail horsepower is available. Below 19 miles per hour, the available horsepower falls off essentially in proportion to speed, whereas above 58 miles per hour, the braking is restricted to 2,000 horsepower. Figure 6 shows the characteristic curve of available braking effort versus miles per hour.

The braking resistors are force ventilated by axial-flow blowers driven by a series motor which obtains its power

through a permanent connection across part of the resistor. Thus, maximum resistor ventilation is obtained automatically at the maximum braking rate. Figure 7 illustrates one of the blower units, a current standard General Electric model *GY-19*, showing the dual-fan contravane assembly integral with the driving motor. There are two such units on the locomotive.

A-C Auxiliary System

Entirely aside from such functions as cab heaters, train control, battery charging, and so forth, more than a dozen different auxiliary operations must be performed, powered by electric motors. In order to have the highest degree of reliability and a minimum of maintenance, as many of the auxiliaries as possible are driven by 3-phase induction motors; see Table I.

A 6-pole 3-phase alternator driven through a flexible steel-disk coupling from a shaft extension on one of the main traction generators furnishes power for the a-c system. Inasmuch as the power plant operates at variable speed, depending upon loading, the frequency of the system will vary between 80 and 48 cycles. The rated voltage of the system was chosen as 290 volts, 80 cycles so that normal motor flux conditions would prevail when checking or testing with standard 220-volt, 60-cycle power.

Class *B* insulation is applied on all this equipment. In order to reduce size and weight, the designs are such that the temperature rises are somewhat in excess of those encountered in normal industrial practice. However, in view of limited field experience with this line of apparatus, the temperatures were kept well below the AIEE standards for transportation equipment. In all cases where the motors may operate in dirty or oily atmospheres, the totally-enclosed fan-cooled construction has been used.

The motors are permanently connected across the alternator. One of the first steps in the procedure of starting the main power plant is to excite the alternator field. As the plant is started from rest and brought up to speed, each auxiliary motor, according to its break-away torque requirements, will begin turning at between 3 and 13 cycles of applied frequency, and from then on come up in speed along with the main power plant. There is no modulation of the alternator field. The unit is of the self-regulating type with sufficient capacity, in case of emergency, to start the largest motor at full frequency and rated excitation without the voltage dropping to the point where other loaded motors may stall. The alternator is nominally rated at 150 kva, 80 per cent power factor, 1,600 rpm, 290 volts, 3-phase 80 cycles.

The traction-motor blowers are perhaps the most unique of the a-c auxiliary equipment, involving special development for this locomotive. The basic locomotive design is such that the traction-motor ventilating air must be furnished through restricted duct work involving high pressure drops. Blower requirements indicated a fan rated 5,375 cubic feet per minute at 8.5 inches of water static pressure. This delivery is obtained by the use of a $16^1/_2$-inch diameter 24-blade single-stage axial-flow fan at 4,650 rpm. The fan, contravane, and 15-horsepower motor are assembled as a self-contained unit. The motor core and windings are totally enclosed. Cooling is obtained from the high-velocity air flow passing over the outside of the motor frame. Rotation is about the vertical axis. In order to insure satisfactory bearing lubrication at the high rotational speed, metered oil lubrication features were utilized for both bearings.

Figure 8 shows the assembled blower unit. Air inlet is through the top and sides of the expanded metal cover. As much inlet area as possible is provided in order to reduce entrance velocities, thus minimizing the tendency to accumulate dirt in the traction motors.

Table I

Function	Horsepower	Revolutions Per Minute
1 fuel sump pump	3	1,150
1 fuel booster pump	3	1,130
1 lubricating oil pump	8.5	1,525
1 coolant pump	5	2,335
2 coolant radiator fans	6 each	1,140
4 amplidyne exciters	8.5 each	2,340
4 traction-motor blowers	15 each	4,650

D-C Auxiliary System

The auxiliary functions which must be in operation prior to and during power-plant starting, before a-c power is available, are handled by an entirely separate d-c system. Such operations as lighting, locomotive and fuel heating, control, and turbine cranking are in this category. This system is centered about a 75-volt storage battery and two identical d-c auxiliary generators. One of these is driven through a flexible steel-disk coupling from a shaft extension on one of the main generators. The other is driven by a diesel engine and, normally, is on the system only when the main power plant is not in operation.

The battery is a 32-cell lead-acid type having 426 ampere-hour capacity. It must furnish the auxiliary power required during the period of power-plant cranking, and accordingly was chosen to have ample capacity to handle at least three successive starts without the necessity of recharging.

The auxiliary diesel-driven generator also furnishes power to one of the main generators operating as a motor. This occurs during power-plant cranking wherein approximately 140 kw is developed when driven by the 210-horsepower 2,100-rpm diesel engine. This cranking power is applied up to over 50 per cent speed until the power plant is self-sustaining by its own developed power. For this application, the generator is rated at 210-horsepower input, 310/180 volts, 460/700 amperes, 2,100 rpm. For battery-charging service, both the diesel-driven generator and the identical turbine-driven auxiliary generator are rated 50-kw output, 75 volts, 667 amperes, 800 to 1,600 rpm. The generators are designed to permit a conventional voltage regulator to operate with stability over an 800- to 1,600-rpm speed range.

Part of the power-plant shutdown sequence involves cranking at approximately 7 per cent speed to equalize various power-plant temperatures. This is done at 75 volts, thereby enabling the diesel-driven generator to charge the battery at the same time.

One significant function operated from the d-c auxiliary system is the stand-by lubricating oil pump. Prior to power-plant starting, the main lubricating oil is heated and circulated throughout the system by a pump driven by a 75-volt

Figure 8. Traction-motor blower unit

Figure 9. Layout of apparatus for a 4,500-horsepower gas-turbine electric locomotive

motor. This pump also serves as an automatic stand-by during locomotive operation in the event of failure of the a-c motor driven pump.

Table II is a general listing of the various motors and generators connected with the auxiliary d-c system.

Table II

Function	Power	RPM
1 diesel-driven generator	50 kw	800 to 1,600
1 turbine-driven generator	50 kw	800 to 1,600
1 stand-by lubricating pump motor	13 hp	1,550
1 400-cycle control motor-generator set	3 hp	3,600
1 water booster pump motor	3 hp	1,750

An additional 25 kw is furnished for various other auxiliary services including heating boiler, lights, cab heaters, defrosters, train control, battery charging, and field excitation.

Conclusions

As is to be expected, the advent of the gas-turbine power plant as a prime mover, with its accompanying light weight and small space per-unit horsepower, tends to focus more attention upon the electric rotating equipment, from the standpoint of the over-all locomotive design.

This is evidenced by its predominance in the locomotive as shown by layouts of Figure 9 where the electric rotating equipment is silhouetted. This apparatus makes up approximately 25 per cent of the weight of the locomotive; 22 per cent of which is for propulsion, and 3 per cent for auxiliary drives. It is of interest to point out that the propulsion equipment, including gear box, main generators, and traction motors weighs approximately 22 pounds per horsepower. This compares with the value of 25 pounds per horsepower for a typical diesel-electric freight locomotive of comparable axle loading.

Based on tests and locomotive operation to date, it is felt that all functions are being performed in a highly satisfactory manner. Fundamental difficulties have yet to appear in any of this equipment, either performance-wise or from a general maintenance standpoint. This is in spite of many exceptional overloads and abuses attending the various initial tests of a special nature which have been part of the performance evaluation of the power plant and locomotive to date.

No Discussion

Rectifier-Type Motive Power for Railroad Electrification

L. J. HIBBARD
MEMBER AIEE

C. C. WHITTAKER
NONMEMBER AIEE

E. W. AMES
ASSOCIATE AIEE

TESTS on rectifier motive power equipment which have been announced recently[1] constitute a very important development in the electrification of steam railroads. Not only does this development mark another important step of progress in the use of electric energy as motive power on railroads, but it forms another practical demonstration of the inherent flexibility of the single-phase a-c system for railroad electrification.

The chief advantage of present d-c electrifications lies in the use of d-c series traction motors on the motive power units.

The fundamental advantage of the single-phase a-c system is its ability to use a high-voltage trolley wire, thus making it possible to supply, economically, large blocks of power over long distances for heavy concentrations of traffic.

Three types of motive power units have been built to operate from an a-c system, namely, the a-c series-motor type, the split-phase type, and the motor-generator type.

The a-c series motor motive power unit is well adapted to any application. The best present-day examples of a-c series motor locomotives are the Pennsylvania Railroad class *GG1* and the New York, New Haven, and Hartford Railroad class *EF3*. Although these locomotives are officially rated at 4,620 continuous horsepower, each can deliver from 8,000 to 9,000 maximum horsepower if occasion arises. These ratings are outputs at the rail. Output in excess of the continuous rating can be delivered at the rail over the entire speed range of the locomotive.

Another important asset of the a-c series motor motive power unit lies in the simplicity and flexibility of the locomotive control system, that is, voltage control, which means a minimum of accelerating losses, a minimum peak power demand, and a large number of running speeds.

The motor-generator motive-power unit combines all the advantages of the flexible high-voltage single-phase a-c trolley system and the advantages of the d-c traction motor with the simplicity and flexibility of voltage control, but it does not have the ability to produce economically high short-time accelerating horsepowers at high speed since the best proportions of the motor-generator set produce a motive power unit with constant horsepower characteristics.

The rectifier motive power unit combines all the advantages of the high-voltage a-c trolley system with the simplicity and flexibility of voltage control plus the advantage of the d-c traction motor and it has the ability to develop high accelerating horsepowers at high speed even more economically than is possible with the a-c series motor motive power unit.

Thus the rectifier motive power unit furnishes an attractive means of utilizing the power which can be delivered to it by a flexible high-voltage single-phase a-c trolley.

Advantages

The advantages of rectifier motive power are summarized in the following:

Rectifier Motive Power versus Single-Phase Series-Motor Motive Power

The rectifier motive power unit has the following advantages on a 25-cycle trolley system. Some of these advantages will be increased if a 60-cycle trolley system is used.

1. Lower weight of equipment.
2. Less space required for equipment.
3. Higher running efficiencies and less standby losses.
4. Higher power factor.
5. Less maintenance. This point must be proved in service. However, the higher efficiency (which means less watt hours per ton mile) plus the reduced maintenance of the traction motor and gearing should easily overbalance the added maintenance of the rectifier equipment.
6. Superior tractive effort rating and tractive effort characteristics. Westinghouse standard diesel locomotive motor type *370-F* with 15/63 gearing on 42-inch wheels (65 miles per hour top speed) will develop 10,700 pounds tractive effort continuously up to 17.5 miles per hour. This is a much greater tractive effort and a higher speed than is possible with an a-c series motor. The speed-tractive effort characteristics of the rectifier motive power unit are similar to the speed-tractive effort characteristics of a motor-generator locomotive (that is, they are flat) and hence should have the same antislip features now enjoyed by the motor-generator locomotive. The rectifier motive power unit can be applied safely at higher adhesions than is permissible for a-c series-motor motive power. The net result of these tractive effort advantages means that fewer axles will be needed for a rectifier motive power unit to meet a given duty cycle than will be needed for the single-phase series-motor motive power unit.
7. Rectifier motive power will develop its continuous horsepower rating at approximately 30 per cent of its top speed, whereas most a-c series motor motive power units do not develop their continuous horsepower rating until they reach 50 to 60 per cent of top speed. This characteristic plus its ability to produce economically high accelerating horsepower at high speed makes rectifier motive power ideally suited for use either in freight or passenger service.

The rectifier motive power unit can be used under a 60-cycle trolley. The rectifier motive power unit can be used interchangeably between two trolley zones involving:

Paper 50-81, recommended by the AIEE Land Transportation Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, January 30–February 3, 1950. Manuscript submitted November 2, 1949; made available for printing December 6, 1949.

L. J. Hibbard, C. C. Whittaker, and E. W. Ames are with the Transportation Engineering Department of the Westinghouse Electric Corporation, East Pittsburgh, Pa.

1. Two frequencies, 25 cycles and 60 cycles.
2. Alternating current and direct current.

The rectifier motive power unit permits more horsepower capacity per cab than any other type.

Rectifier versus Motor Generator Motive Power

The rectifier locomotive has the following advantages:

1. Less weight of conversion equipment.
2. Less cost of conversion equipment.
3. Less space requirements for the conversion equipment.
4. More capacity per cab permitted.
5. Simpler and cheaper mechanical parts because of item 3.
6. Reduced standby losses and higher operating efficiencies.
7. High accelerating horsepowers at high speeds.

Rectifier versus Diesel-Electric Motive Power

The price of electric energy has been relatively stable, whereas the long term trend of liquid fuel prices has been upward. Where economic conditions justify the electrification of a dieselized railroad, the diesel electric locomotives can be transformed into rectifier locomotives by removing the diesel engines and their appurtenances and applying pantographs, transformers, auxiliaries, and rectifier equipment.

The rail horsepower rating of most diesel electric locomotives can be substantially increased when and if such a change is made.

History

The desirability of producing a system of electrification embodying the advantage of high-voltage a-c transmission with low-voltage d-c traction motors has been a dream of transportation engineers ever since Westinghouse, in the year 1914, first ran a rectifier car in revenue service on the New Caanan branch of the New York, New Haven, and Hartford Railroad. This car was equipped with a multianode pumped-type rectifier. Two fundamental limitations were encountered in the use of this car as a motive power unit.

It was limited by the requirement of pumping to maintain the vacuum in the rectifier. At that time, the technique of vacuum pumping and vacuum seals had not reached the present stage of perfection.

The car produced telephone interference and it was necessary to install

Figure 1. Explanation of ripple

track booster transformers in the test section to force all the trolley current to return through the rail.

Prior to 1937, all rectifiers were of the multianode pumped type, with as many as 18 anodes per tank. Subsequently, two developments, the sealed tube[2] and the ignitor, combined with a single anode made the application of sealed tube ignitrons to moving vehicles particularly attractive. With the great impetus which World War II gave to the production of aluminum and magnesium by the use of ignitrons, which supplied large amounts of d-c power, the ignitron was produced in quantity. Concurrently, the large demand for diesel electric locomotives has similarly put the low-voltage d-c traction motor into mass production. Hence rectifier-type motive power becomes a product which will be benefited greatly by these two high-production items.

In the past, three main problems have deterred the use of ignitrons and other forms of rectifiers on rectifier motive power units:

1. The effect of shock and vibration encountered on a moving vehicle with respect to the strength of ignitron tube parts, and with respect to the effect of a turbulent mercury pool on the performance of the ignitors.
2. The effect of the ripple in the rectified single-phase current wave form with respect to the heating and commutation of conventional d-c motors.
3. The effect of interference with communication circuits when operating from a single-phase trolley with ground return.

Laboratory Tests

Problem 1 was approached by determining the maximum values of acceleration forces expressed in terms of g (acceleration of gravity) observed on an electric locomotive classified as a satisfactory riding unit. These values were: maximum cab lateral observed, 0.66 g; usual cab lateral, 0.16 g. Both values were read on curved track at 95 miles per hour. Cycles of oscillation were 78 per minute.

Similar tests on another locomotive classified as an unsatisfactory riding unit indicated that the usual cab lateral was approximately 0.32 g while the frequency at 90 miles per hour was 114.

Based on the above, an oscillating test table was made on which the ignitrons were rigidly mounted. This table had an amplitude of vibration which could be varied from one to three inches and a frequency which could be varied up to 250 cycles per minute, giving values as high as 1.8 g acceleration, or well in excess of those observed on a rough-riding locomotive.

With this laboratory setup, two standard type *WL-653-B* ignitron tubes, mounted rigidly on the shaking table, delivered 200 to 800 amperes to a Westinghouse type *362* railway motor while shaking at a frequency of 120 cycles per minute and one-inch amplitude. This particular railway motor is standard on Westinghouse 660- and 1,000-horsepower diesel electric switcher locomotives. At this shaking frequency no misfires occurred during several hours of operation. By a misfire is meant failure of the ignition circuit to start an arc for one or more half-cycle waves. One or several misfires in traction service would not be more serious than a pantograph bounce of short duration. This test was continued for several months, and no weakness was apparent in the design of the tube when exposed to these severe tests.

Problem 2 deals with the effect of ripple on commutation and heating of the traction motors. By ripple is meant the amount of deviation from a straight line wave form of rectifier current. See Figure 1.

Tests on the type *362* motor were made at various loads and at various ripples in the power supply as affecting commutation. This motor is rated at 510 amperes, continuous on 310 volts.

With a d-c circuit reactor to limit the ripple, the results shown in Table I were obtained.

A temperature test was made on the type *362* motor using rectified current with a 30 per cent ripple. This test showed a temperature increase in the motor windings of from 1 to 2 per cent over the results obtained with generated d-c power.

Tests with rectified current also were conducted on two other traction motors, one a type *1447* used on the New York Board of Transportation subway cars and the other a type *559-DR3* used on the Long Island Railroad cars. Both of those motors showed equally as good commutation and stability as the type *362*.

Problem 3, pertaining to possible telephone interference, was studied in the laboratory. The type *362* motor was operated at 600 to 700 amperes with a single-phase ignitron. The harmonic content of the single-phase line current feeding the single-phase ignitron was measured by means of a harmonic analyzer.

In order to have a single-phase full-wave rectifier produce a square wave alternating current, the following theoretical conditions are required:

1. Infinite inductance in the d-c circuit.
2. Zero angle of overlap.

This means that each half a-c wave must be a square wave. The square a-c wave can be expressed mathematically by the Fourier series as follows:

$$e=\frac{4E}{\pi}\left(\sin\ \omega t+1/3\ \sin\ 3\ \omega t+1/5\ \sin\ 5\ \omega t \ldots\ldots+\frac{1}{n}\sin\ n\ \omega t\right)$$

Table II. Harmonic Currents for Various Values of *IT*

Harmonic	Frequency	Calculated Square Wave Current, Amperes	Test Amperes, Dec. 16, 1947	Test Amperes, Feb. 3, 1948

IT		165,000	16,700	357

where

e = instantaneous value
E = crest value
$\omega = 2\pi f$
f = fundamental frequency
n = any odd integer
t = instantaneous value of time

The term *IT* is used to indicate the intensity of telephone interference. Briefly, it is the product of current by *T*, a weighting factor which is dependent upon the frequency, coupling, and sensitivity of instruments and of the human ear.

The calculated *IT* product of a 25-cycle square wave having 210-ampere fundamental is 165,000 based on the 1935 weighting. This is a very high value of *IT* and taken by itself would tend to discourage the use of rectifier motive power. However, it is not possible to obtain infinite inductance in the d-c circuit or zero angle of overlap in the a-c circuit.

In order to approach with practicable test equipment the theoretical square wave conditions, all the available suitable inductance in East Pittsburgh for the d-c circuit was utilized and the ignitrons were energized at a point where there was very little reactance in the power circuit. With this special setup, the maximum *IT* value obtained by test was approximately 10 per cent of the calculated *IT* value.

With the aid of practicable filtering means, the *IT* value for 210 amperes fundamental was reduced to 357.

Figure 2. Rectifier test car main circuit

Table II gives a picture of the various harmonic currents involved for the conditions mentioned previously.

Tests on Pennsylvania Railroad

Laboratory tests were so favorable that it was decided to make tests in service under actual electrification operating conditions. Co-operation of the Pennsylvania Railroad was sought for the assembly of propulsion and control apparatus furnished by Westinghouse Electric Corporation and the multiple-unit car and its auxiliary apparatus by the Pennsylvania Railroad Company. This assembly has been in trial performances for adjustment and refinement of apparatus for some months. The car now is in revenue service.

In addition to this procedure, the Bell Telephone Laboratories and the American Telephone and Telegraph Company co-operated with Westinghouse and the Pennsylvania Railroad in conducting a series of tests to determine the telephone noise influence aspects of the rectifier car and existing single-phase a-c series motor equipment.

The results of telephone noise influence tests are still in preliminary form and are not contained herein.

Description of Car and Control

This car was a combination type, half its length being a baggage compartment. All test equipment requiring adjustment and observation, instruments, and oscilloscopes were mounted in this baggage compartment.

The electric equipment consisted of a specially-designed transformer, four type *WL-653-B* ignitron tubes for single-phase full-wave rectification, plus a variety of capacitors and reactors as variable test equipment. Two Long Island-type traction motors with control boxes and accelerating grids were used primarily because they could be secured quickly. In the future on an a-c road, voltage tap control from a transformer would be used.

The main circuit schematic for the test car as it was placed in revenue service at the completion of the harmonic tests is shown in Figure 2.

Preliminary Test Results

This rectifier car was initially energized on July 15, 1949, since which time it has been under limited operation for apparatus refinement and adjustment with no fundamental difficulties ascertained in approximately 2,500 miles of trial. It was placed in revenue service on October 26, 1949. Since then to April 15, 1950, the car has been trouble-free, has operated 26,000 miles, and is in the multiple unit car pool, going wherever dispatched.

Problem 1

Shock and vibration during normal operation has not affected operation in the least. The car has been operated most of the time during the tests pulling a second car as a trailer. It has been operated successfully for sustained periods of time with full-wave rectification from two tubes only, first one pair of tubes were used up to 60 miles per hour for 25 successive accelerations, then the other pair of tubes were used in the same manner. Normally all four tubes would be used. It has been operated intentionally for short periods of time on two tubes with half-wave rectification.

Problem 2

The motors have been operated most of the time with approximately 33 per cent ripple in the direct current. The commutation under these conditions has been black at all times and the commutators and brushes have an excellent appearance. Limited testing was done with a 5 per cent and a 55 per cent ripple.

The test car was operated for three round trips making all stops between Broad Street Suburban Station, Philadelphia and Paoli with approximately a 33 per cent ripple in the direct current. The three round trips were repeated the next day with a 5 per cent ripple in the direct current. Both tests resulted in an 86 degree centigrade rise (by thermocouple) in the interpole winding.

Problem 3

The telephone influence of such a rectifier is being investigated on a 25-cycle system. The results, though not complete, include field test data taken on the ignitron-equipped multiple-unit car. They indicate that practical filters can be produced which will permit the use of rectifiers as a power supply for individual traction units of an electrified railroad system paralleling associated and commercial communication circuits.

The authors are confident that practical filters can be built to permit the operation of rectifier motive power on 60-cycle trolleys in parallel with shielded communication circuits.

Summation

A great deal of engineering data has been collected during our laboratory tests and tests are still in progress. Also a great deal of engineering data was taken during our joint car tests with the Bell Telephone Company and Pennsylvania Railroad.

Figure 3. Section Drawing of Ignitron Tube

These data cover numerous tests on different filter combinations and constants and the effect of these constants on telephone interference compared with the interference generated by one of the cars equipped with single phase series motors.

The laboratory test data and the car test data are being correlated and analyzed but with only preliminary results available at this writing. It is hoped that the information can be presented jointly by the parties involved at some time in the future.

A full discussion of the problems involved cannot be made until the foregoing analysis has been completed.

It is confidently predicted that rectifier motive power units will find wide use on present electrified systems and will hasten the electrification of additional railroad mileage.

Discussion

D. R. MacLeod (General Electric Company, Erie, Pa.): The important fact in this paper is that once again a single-phase rectifier multiple-unit car is in revenue service energized from a 11,000-volt 25-cycle trolley. This test will answer several questions which can be answered only by extended operation in revenue service. The test is in the competent hands of two engineers who have had long and varied experience in a-c traction development and is being conducted under the watchful eyes of the engineers of the railroad which has had more experience than any other in pioneering developments in a-c traction. We applaud this effort to advance the art and offer our congratulations to the men who by their faith, skill, and perseverance have made the test possible.

The relationships of some parts of the contents of the paper are not clear to me. As I interpret the tabulation of harmonic currents, they are at 11,000 volts so that the tests of February 3, 1948, for example, represent 2,376 kva. As this is far greater than the maximum kilovolt-ampere input required by a single Pennsylvania Railroad multiple-unit car, the conclusion is that the tabulated results in the paper do not bear any relationship to the equipment that is in operation on the Pennsylvania Railroad. It would be helpful to know what the current harmonics were on the 11-kv side of the transformer on the car at the point where all the resistance in the controller was cut out, or at some other well defined connection at which the data were taken. It also would be helpful to know what per cent ripple there was in the current supplied to the d-c motors corresponding to the harmonics measured in the 11-kv input current.

C. C. Herskind (General Electric Company, Schenectady, N. Y.): This paper is of interest as it represents an application of mercury arc rectifiers that has been dreamed about for many years. Not only did engineers consider the use of rectifiers on a railway car at a very early date, but the subject has been revived from time to time.

As recently as 1944 General Electric engineers made extensive tests on sealed ignitrons under shock and vibration conditions simulating those encountered in railway service. At the same time load tests were made on d-c traction motors supplied from a 2-tube rectifier. These tests were made to establish the basic factors that affect the operation of d-c traction motors on a single-phase rectifier circuit.

In addition to the motor heating and commutation problem, there remains the problem of wave shaping. The 2-tube rectifier delivers two sinusoidal pulses of voltage to the motor load every cycle. In order to obtain smooth direct current, a large inductance is placed in series with the load. The rectifier, therefore, delivers square waves of current to the load. But these square waves also appear in the a-c lines where they must be reshaped to sinusoidal form.

The necessity for shaping the waves, that is, filtering on both d-c and a-c sides presents a serious space, weight and cost obstacle. Perhaps satisfactory wave shapes can be readily obtained on a single-car equipment. However, when a large number of cars operate on a 25-cycle system so that their combined load is a substantial part of the system capacity, more perfect filtering will no doubt be required in order to avoid excessive wave deformation. It would appear that the wave distortion caused by the 2-tube rectifiers may result in trouble both from telephone interference, generator heating, and system over-voltages. We would appreciate the author's comments on this problem.

L. F. Roehmann (Anaconda Wire and Cable Company, Hastings-on-Hudson, N. Y.): In 1935 and 1936 the German Reichs Railroads embarked upon a rather interesting experiment. They electrified two sections, totalling about 35 miles, of the Hoellentalbahn, in the Black Forest, with 50 cycles-per-second single-phase alternating current which was taken, by means of a Scott-connected transformer, from the public 3-phase supply system. Four experimental locomotives were built for this service, two of them (built by Allgemeine Elektrizitats Gesellschaft and Brown Boveri and Company) units with steel-tank rectifiers and d-c traction motors. A short description of this work was given by the discussor in Railway Age of August 28, 1937,[1] where a photo of the Brown Boveri locomotive is shown.

At that time, I was interested in the inductive co-ordination aspect of this work. After leaving Germany, and due to the war, I lost track of subsequent developments. However, I am sure that valuable information of both the power and the inductive interference aspects can still be secured. I recommend that this be done and that the experience be used to good advantage for the work now in progress in this country. As to inductive interference, it should make no difference whether the direct current for the traction motors is obtained through ignitrons, or from a multianode rectifier.

1. Electrification at Commercial Frequencies, Ludwig F. Roehmann, *Railway Age* (New York, N. Y.), volume 103, number 9, August 28, 1937, page 273.

P. A. Jeanne (Bell Telephone Laboratories, Inc., New York, N. Y.): The Bell Telephone Laboratories appreciated the opportunity afforded by the Pennsylvania Railroad and the Westinghouse Company to take part in the tests of the rectifier motive-power unit described in the paper by Mr. Hibbard and his associates. Comprehensive noise influence measurements of the small rectifier powered unit used in the Pennsylvania Railroad tests were made together with comparative tests of the influence of the present conventional motive power.

From these data, it is hoped to reach a reasonably reliable estimate of what would be expected in the way of influence from a large rectifier powered passenger or freight locomotive operating at 25 cycles. Also, it is hoped that these estimates may be supplemented by actual tests of such a large locomotive. The authors feel that they also can successfully filter rectifier power equipment operating at 60 cycles.

This frequency of operation is naturally of more concern to communication engineers because the important harmonics produced in the a-c supply to the rectifier fall higher in the voice frequency range where the influence per ampere of current is more important, and because 60-cycle systems from which the railway would draw its power might also be involved in close exposures with communication lines. We are, therefore, somewhat less optimistic regarding the possibilities of successfully mitigating inductive interference from 60-cycle operation than we are concerning 25-cycle operation and will welcome any opportunity to check results in field tests.

L. J. Hibbard: In reply to D. R. MacLeod's discussion we wish to state the test amperes of February 3, 1948 represent the approximate line amperes for a 5,000-horsepower locomotive under a 24,000-volt trolley. The inductance in the d-c motor circuit was adjusted to give approximately a 30 per cent ripple in the direct current for this test.

The harmonic measurements made during the joint tests last summer were obtained with Bell Telephone Laboratory noise meters which gave the *IT* product due to all harmonics but did not give a measure of the individual harmonics.

Typical *IT* products obtained with these noise meters during our tests are given in Table I of the discussion.

With reference to C. C. Herskind's discussion, we do not expect all the harmonics from a large number of rectifier motive power units operating simultaneously on an

electrified railroad to add up arithmetically. The phase angle between the line voltage and the locomotive transformer line amperes on various rectifier motive-power units will vary a few degrees for each different trolley location.

If we assume that the fundamental amperes of one motive power unit lags 4 degrees 23 minutes behind the fundamental amperes of a second motive power unit, the phase difference between the two groups of harmonics associated with each of these fundamentals will rapidly increase as the frequency of the harmonic increases.

If the fundamentals are 4 degrees 23 minutes apart, the third harmonics will be approximately 13 degrees 9 minutes apart, the fifth harmonics will be approximately 21 degrees 55 minutes apart, the seventh will be approximately 30 degrees 41 minutes apart, the ninth will be approximately 39 degrees 27 minutes apart, and so forth, and the 41st harmonics will be approximately 180 degrees apart.

In the case of adjacent motive-power units, we can set up the motive-power unit circuit constants or angle of delay in firing to insure a few degrees difference in the phase position of their line ampere fundamentals.

Table I

Car and Status	Telephone Interference *IT* Product—1935 Weighting Measured on Test Train Maximum
412 motor car	2,500
Rectifier car—without filters	1,800
Rectifier car—with filters	280

Likewise in the case of independent rectifier units on a given motive-power unit, we also can set up a few degrees difference in the phase of their fundamental amperes received from a common transformer.

The author wishes to thank Mr. Roehmann for his discussion.

Westinghouse representatives from East Pittsburgh and England visited the Hoellentalbahn Black Forest 50-cycle electrification recently and report that the rectifier motive power units are performing successfully.

They also report that telephone conversation over the railroad's telephone system was perfectly satisfactory while the rectifier locomotives were drawing current from the line.

The writer has no knowledge of any noise measurements or harmonic analyzer measurements being made by the Germans on this rectifier locomotive application.

Mr. Jeanne's discussion was very interesting. We hope to obtain joint noise tests on a 25-cycle rectifier locomotive some time during 1951 and have hopes of obtaining tests on a 50-cycle or a 60-cycle rectifier motive power unit a few months thereafter.

Future 60-cycle railroad electrifications will almost surely involve higher trolley voltages and the writer expects to see the trolley voltage approach 50,000 volts.

A 5,000 horsepower 25-cycle locomotive will draw approximately 400 amperes at 12,000 volts, while a 5,000-horsepower 60-cycle locomotive will draw approximately 100 amperes at 48,000 volts.

Hence, an increase in trolley voltage from 12,000 volts to 48,000 volts will reduce the trolley current sufficiently to largely offset the increase in *IT* product caused by the fact that the important harmonics (for 60-cycle trolley) fall higher in the voice frequency range

New Lightning Arrester Standard

H. R. STEWART
FELLOW AIEE

F. M. DEFANDORF
FELLOW AIEE

FOR the past several years there have been three separate AIEE Standards bearing on the lightning protective devices field; namely, Report on Proposed Standard for Protector Tubes, American Standards for Lightning Arresters for Alternating Current Power Circuits, and Proposed Standard for Expulsion Type Distribution Lightning Arresters,[1,2,3] all prepared under the sponsorship of the AIEE Protective Devices Committee. By the time of the publication of the last Standard mentioned above, it was evident that there was much material in these various Standards which had a common application, and many of the definitions and test procedures were common. W. J. Rudge, then Chairman of the Lightning Protective Devices Subcommittee of the Protective Devices Committee, perceived the advantages of merging all three Standards, and set up a working group for such a project. It was believed that the combining of Standards on lightning protective devices should not only lead to improved nomenclature but would bring into sharper focus the inherent characteristics of the different species of lightning arresters, and at the same time would improve the accessibility of desirable information.

Early in the course of the undertaking, the Working Group* encountered a tendency to incorporate in the Standard material which was of considerable importance in the proper application of lightning arresters. After very careful consideration by the Lightning Protective Devices Subcommittee, it was the consensus of opinion that inasmuch as this material concerned primarily the nature of the associated circuits and lines, a separate project be set up to devise a suitable application guide for lightning arresters that would fulfill the needs of the user more completely than one could hope for by inclusion of a few precautionary suggestions in the Standard. Even with this desirable simplification, the working group of users' and manufacturers' engineers found a number of loose ends to tie together in their task of improving and combining, through nine drafts, earlier efforts into a single standard.

A perusal of the definitions in the new Lightning Arrester Standards for Valve and Expulsion Arresters,[4] will show several differences adopted primarily to improve clarity and definiteness of expression. These new definitions have been correlated with the current revision being made in American Standard Definitions of Electrical Terms.[5]

It will be noted that the term "protector tube" has been superseded by "expulsion arrester" so that all devices covered by the new Standard are referred to as "arresters" of one type or another. Classifications such as "station type," "line type," "distribution type," and "secondary type" are not defined in the Standard, and it is left to the maker to apply such designations. However, the Standard does state the appropriate tests to apply to lightning arresters of these various classifications.

In the matter of discharge current withstand tests (formerly called discharge capacity) of lightning arresters and prorated sections, the requirements have been altered to bring them in line with tests that can be performed in existing laboratories. The formerly-specified 5 by 10 wave (with stated tolerances) has been changed to "a surge current with wavefront duration between 5 and 10 microseconds and wave-tail between 10 and 20 microseconds" having crest ampere values of 100,000 for station....., 65,000 for line and distribution, and 10,000 for secondary-arresters, it being specified that tests shall be on complete lightning arresters up to 9 kv or prorated characteristic elements whose ratings are 3 kv or greater, but need not exceed 9 kv. This restatement is in better accord with laboratory tests that can actually be made with existing surge-testing equipment.

With respect to duty cycle tests on expulsion lightning arresters, it is recognized that the severity of the test is very dependent on the voltage recovery rate of the test circuit. However, with the past lack of knowledge of the range of recovery rates on the circuits on which these devices are used in service, particularly on distribution circuits, it has not been possible to include in the Standard any specified voltage recovery voltage rates for the duty cycle test circuit with any assurance that they would reflect conditions found in service. At the present time a Joint Working Group of the Transmission and Distribution Committee and of the Lightning Protective Devices Subcommittee appointed to study rates of rise of recovery voltage on distribution systems has made considerable progress on this matter, both by field and laboratory tests. It is expected that the results of this broad-scale study will be valuable not only in the future revision of lightning arrester Standards but also to standardizing groups interested in fuses and other distribution type interrupting devices.

Similarly, it has not been possible to

The new Standard covered by this paper, Lightning Arrester Standards for Valve and Expulsion Arresters,[4] was prepared under the sponsorship of the AIEE Protective Devices Committee, G. B. Dodds, *chairman*, and its Lightning Protective Devices Subcommittee consisting of H. A. Cornelius, F. M. Defandorf, R. H. Earle, Milan Getting, I. W. Gross, E. H. Grosser, H. W. Hartzell, T. H. Mawson, T. I. Eldridge, W. A. McMorris, A. M. Opsahl, W. E. Rushlow, A. H. Schirmer, J. M. Towner, E. R. Whitehead, E. H. Yonkers, and H. R. Stewart, *chairman*.

include in the new Standard[4] any values for radio influence tests due to lack of knowledge of requirements and pending extensive work by various industry groups needed before Standards can be formulated.

It will be noted that for special lightning arresters used for the protection of rotating machinery, the acceptance tests as to the current magnitude at which the discharge voltage test is made and the rate of rise of voltage for the impulse sparkover test are lower than those respectively required for Standard lightning arresters. This is in recognition of the fact that these special lightning arresters are usually applied in conjunction with wave sloping capacitors which materially change the service conditions under which the lightning arresters are called upon to operate.

Table I of the Standard specifying withstand test values for the assembled insulation of lightning arresters represents a considerable change from the similar table in Standard Number 28. Whereas the earlier Standard stated that "Where application is to be made of an arrester having a lower voltage rating than the rated voltage of the circuit on which it is to be used, such as on grounded-neutral circuits, the insulation test shall be that specified for the insulation class one step lower than the rated circuit voltage," the new Standard includes these intermediate ratings in the listed lightning arrester voltage ratings and assigns to them withstand test values which are interpolated between withstand test voltages assigned to the formerly listed next higher and lower ratings, each of which corresponds to Standard Basic Insulation Levels. It will be noted that no insulation classifications are assigned to these intermediate lightning arrester ratings.

The inclusion of the intermediate lightning arrester ratings in Table I in this manner is a compromise solution of a very difficult problem on which widely diverging views were held. One view was that whereas grounded neutral circuits usually are built with full insulation, grounded neutral lightning arresters used on those circuits also should have full insulation rather than insulation conforming with one basic insulation level step lower. On the other hand, this might mean a redesign of some of the intermediate voltage rating lightning arresters if they should conform to the basic insulation level of the fully insulated circuit on which they are used. Since a general redesign of lightning arresters may be imminent if the present deliberations of the Joint AIEE-EEI-NEMA Committee on Insulation Co-ordination should result in a revision of present Basic Insulation Levels, it did not seem wise to call for insulation values in the new Standard which would necessitate a possible interim redesign. It will be noted in view of this activity by the Joint Committee on Insulation Co-ordination that all values in Table I are to be considered, as expressed in a footnote, as interim values subject to revision when the report of the Joint Committee is issued. Also, the addition of the intermediate lightning arrester values to Table I should not be considered as a precedent for adding Basic Insulation Levels to an existing Standard list on the part of groups standardizing tests on individual types of apparatus.

Like all other Standards, the "revised and combined" Lightning Arrester Standard is not presented as the last word but rather as a closer approximation to a desirable Standard. More information as to better tests for Lightning Arresters will always be needed and the Standard will continue to be improved as the result of improved tests.

Surge Protection of Cable-Connected Equipment

R. L. WITZKE
MEMBER AIEE

T. J. BLISS
ASSOCIATE AIEE

THE adequate surge protection of electric equipment connected to overhead lines through cable has been a subject of discussion for many years. The usual question is "How long can a cable be without requiring lightning arresters at the equipment in addition to those at the junction between the cable and overhead circuits?" This question is taking on increasing importance because of the trend toward the use of cable connections in unit substations. This practice has the advantages of decreased congestion in the vicinity of substations and of improved appearance, the latter being particularly important in residential districts. The use of cable does, however, influence the surge protection problem because of the added complications incident to the installation of lightning arresters close to the equipment being protected. With overhead connections, the generally accepted practice is to install lightning arresters as close as possible to the equipment, whereas with cable the more common practice is to install lightning arresters only at the junction between the cable and overhead circuits. The purpose of this paper is to review the latter practice and show the degree of protection afforded.

The general data included in this paper are based on analogue computer studies. Tests made on 15-kv power cable in the Impulse Laboratory showed that very good results could be obtained on the analogue computer. This is fortunate because the use of the analogue computer permits a study of the wide range in conditions that must be considered to obtain a complete picture of this important surge protection problem. The general data included permit an evaluation of the influence of the magnitude and rate-of-rise of surge currents, lightning-arrester discharge-voltage characteristics, cable surge impedance, as well as other factors. Typical oscillograms are included to show the general wave shape of the surges across the equipment.

Tables of permissible cable lengths are included for switchgear assemblies and oil-insulated transformers in the voltage classes up to, and including, 34.5 kv. These tables are based on surge currents with a 10,000-ampere crest and a rate-of-rise of 4,000 amperes per microsecond. The cable lengths based on these assumptions, which were considered reasonable and not severe, appear to be short when viewed in the light of experience, especially with oil-insulated transformers. This would indicate that certain probability factors, which are normally neglected, are important in these applications. These might include probable lightning-arrester characteristics and possibly the probable margins in equipment insulation levels for the surges encountered. Available data do not permit a detailed consideration of each of these probabilities at this time. A survey of current practices and experiences may be required before any table of values, completely acceptable to the industry, can be formulated. The tables included in this paper for oil-insulated transformers are believed to be fairly conservative and subject to modification as more data and experience are obtained. The table of values for switchgear assemblies are probably not as conservative as the values for oil-insulated transformers.

Application Guides

The studies reported in this paper are limited to the case of a single overhead circuit connected to a single metallic-sheath cable terminated in a circuit breaker or transformer, see Figure 1. The results thus obtained will be conservative when applied to cases involving a cable terminated in a bus having a multiplicity of circuits. It is assumed that the cable has a continuous metallic sheath bonded to the transformer case, or to the circuit-breaker frame. At the junction end a lightning arrester is connected between a phase conductor and the metallic sheath with leads of the shortest possible length.

Lightning-arrester ground resistances can be neglected because they will not have any practical influence on the conductor-to-sheath voltages in lead-covered cable. The surge characteristics of the transformer are represented by a capacitance, which is permissible for surges of short duration, such as obtained in this investigation. The same representation would apply for cases involving a circuit breaker, the only difference being in the magnitude of the capacitance.

It is assumed that any surge arriving at the junction between the overhead and

A. Discharge voltage less than impulse sparkover voltage

B. Discharge voltage equal to impulse sparkover voltage

Figure 4 (right). Permissible junction-pothead voltage for Class II equipment

cable circuits has a uniform rate of rise. Based on this assumption, the voltage across the junction pothead will have a uniform rate of rise, except with short cables, where reflections from the equipment end may modify the junction-pothead voltage before the junction lightning arrester operates. With the longer cables, the lightning-arrester voltage will increase at a constant rate to the impulse sparkover value and then change to a discharge voltage drop determined by the current through the lightning arrester.

The lightning-arrester voltage will have the general shape shown in Figure 2(A) if the discharge voltage is less than the impulse sparkover voltage, or the shape in Figure 2(B) if the discharge voltage is equal to or greater than impulse sparkover voltage.

The voltage at the junction pothead will include lead drop as well as lightning-arrester voltage. The lightning-arrester leads will have an inductance of approximately 0.4 microhenry per foot, which gives a voltage of 0.4 kv per foot for each 1,000 amperes per microsecond rate-of-rise in the lightning-arrester current. The maximum lead drop will be present as long as the lightning-arrester current is changing at the assumed rate. As the lightning-arrester discharge voltage also is a maximum during the maximum rate-of-rise of current, it is permissible to add the lead drop directly to the lightning-arrester discharge voltage.

The studies are based on the assumption that excepting as modified by reflec-

34.5	200

* Some circuit breakers have lower insulation levels in the open position as indicated by the values in parentheses. It is the intention of the industry to raise these values to the basic levels as soon as design improvements permit.
** The 150-kv basic insulation level may be used in applications where adequate surge protection is provided.

tions from the equipment end of the cable, the total voltage across the junction pothead rises at a uniform rate to a maximum value determined by the lightning-arrester discharge voltage plus lead drop, and that this maximum voltage is maintained for at least twice the cable propagation time. Based on this assumption the total voltage across the junction pothead has the general shape shown in Figure 2(B). The front F is obtained by dividing the maximum voltage across the junction pothead by the rate-of-rise of voltage across the pothead. A front of 0.4 microsecond was used in the analogue computer studies; however, the results are generalized to permit an evaluation of other fronts.

In the cases where the junction-pothead voltage is modified by reflections from the equipment end before the maximum voltage is reached, the front F is defined as the maximum junction-pothead voltage divided by the initial rate-of-rise of voltage. The reflections therefore do not enter into the definition of the front F.

Equipment Insulation Levels

For surge protection purposes it is necessary to differentiate between equipments having only a full-wave test level, and equipments having full-wave, chopped-wave, and front-of-wave levels. Conservative practices will require that the surge voltages be limited to the full-wave level whenever the standards do not specify chopped-wave or front-of-wave levels. In the case of apparatus having higher short-time levels, it should be possible to exceed the full-wave levels when the applied surge is of short duration. For these reasons the equipments normally encountered in cable-connected applications have been divided into two classifications, as follows:

Class I

Switchgear assemblies.
Dry-type distribution and power transformers.

Class II

Liquid-filled transformers.
Dry- and compound-filled instrument transformers.

The basic insulation levels for switchgear assemblies are given in Table I. The levels for dry-type distribution and power transformers are included in Table IV. Protection for Class I equipments should be based on limiting the surge voltages at the equipment to the basic insulation levels.

In the case of Class II apparatus it should be possible to exceed the basic insulation levels in cable-connected applications where the surge voltages are of short duration. The permissible overvoltage, however, should be associated with the wave shape of the applied surge. As these wave shapes vary over a wide range and differ considerably from standard test waves any exact determination of the permissible overvoltage is impossible at this stage of the art. The authors have derived an integration method for evaluating the disruptive effect of surges of nonstandard wave shape. However, the method is not proposed for general application purposes at this time. The authors have chosen to co-ordinate with the chopped-wave level of Class II apparatus, using the integration method as a guide in evaluating the adequacy of the protection provided.

Application Tables. Tables II and III give the maximum permissible cable lengths for Class I and Class II equipments for basic insulation levels between 45 and 200 kv. If these lengths are exceeded in any application, lightning arresters must be installed at the equipment, in addition to those at the junction pothead, or the application should be studied in detail, using procedures discussed in a later section. The tables are based on the following assumptions:

1. Protection is provided for lightning-arrester currents of 10,000 amperes.
2. Lightning-arrester discharge voltages as given in Table VII.
3. Lightning-arrester lead lengths and voltages as given in Table VIII.

Table II. Suggested Maximum Cable Lengths With Class I Equipment

Table IV. Maximum Receiving-End to Sending-End Voltage Ratios for Dry-Type Distribution and Power Transformers

Insulation Class, Kv	Basic Insulation Level, Kv	Lightning Arrester Rating,* Kv	Junction Pothead Voltage	E_r/E_s
1.2	10	3	15.0	0.67
2.5	20	3	15.0	1.33
5.0	25	3	15.0	1.67
3.66	35	6	28.0	1.25
15	50	12	52.0	0.96

* Rating of lightning arrester at junction between cable and overhead circuits.

4. The maximum rate-of-rise of the junction-pothead voltage results from a 4,000-ampere-per-microsecond current surge into the cable, and the cable surge impedances in Table IX.

5. Terminal equipment capacitances of zero or 3,200 micromicrofarads, depending upon which value results in the highest voltage across the equipment.

6. The maximum equipment voltage is limited to the full-wave level for Class I equipment, and to the chopped-wave level for Class II equipment.

In using these tables it is necessary to know the basic insulation level (BIL) of the equipment being protected, and the type and rating of the lightning arrester at the junction between the overhead and cable circuits. The lightning-arrester rating is determined by the system voltage and grounding conditions as in any other application. The cable lengths given in the tables will be shorter than necessary in many cases because of the conservative assumptions that had to be made to obtain a table of values independent of cable surge impedance, equipment capacitance, magnitude and shape of incoming surge, and so forth. Less conservative applications can be made only by a detailed consideration of all the factors involved.

Dry-Type Distribution and Power Transformers. The proposed insulation levels for dry-type distribution and power transformers are given in Table IV. These levels are such that adequate protection cannot be provided without lightning arresters at the transformers, whenever the equipment is connected to exposed overhead lines through cable. Even with station-type lightning arresters at the junction between the overhead and cable circuits, the junction pothead voltage is so high in terms of the transformer levels that adequate protection is not provided even with short cables, unless additional lightning arresters are installed at the transformers. Assuming station-type lightning arresters at the junction between the overhead and cable circuits, the junction pothead voltage based on the lightning-arrester and lead voltages in Tables VII and VIII will be as given in Table IV. Dividing these voltages by the transformer insulation levels gives the maximum permissible receiving-end to sending-end voltage ratios. Comparing these ratios in Table IV with the data in Figure 5 shows that lightning arresters are generally required at the transformers.

A more comprehensive discussion of the protection of these transformers is given in reference 1.

Application Curves. The curves in Figures 3 and 4 give the maximum permissible voltages across the junction pothead for cable lengths up to 1,000 feet. These curves are based on the same conditions as used in preparing the application tables, excepting that no assumptions are made relative to lightning arrester characteristics and lead lengths. These curves permit an evaluation of the influence of lightning arrester discharge voltages and lead lengths on the permissible cable lengths. In a particular application, where the cable length is known, the permissible junction-pothead voltage can be obtained from the curves. A study then is made to determine whether available lightning arresters and possible lead lengths will limit the voltage to this level.

Application of Basic Data

The data in Figure 5 should be used when an application is to be checked in detail. These data are expressed in terms of $(s/v)/F$ and ZC/F ratios, where

s = cable length in feet

v = velocity of surge propagation in feet per microsecond

Z = cable surge impedance

C = equivalent surge capacitance of terminating equipment in microfarads

F = front in microseconds of surge voltage across the junction pothead

Some discussion of these variables is required as a basis for using the data in Figure 5.

The velocity of propagation of surges in power cables depends only on the dielectric of the cable and never varies appreciably from 500 feet per microsecond for oil-impregnated paper-insulated cables. Little general data are available on the effective capacitance of equipment to surges of short duration. Typical values will range between several hundred micromicrofarads for circuit breakers and 1,000 to 3,000 micromicrofarads for transformers. The capacitance C appears in the problem as a product with the cable surge impedance Z, the resulting ZC product being the time constant of the circuit consisting of the cable and the terminal equipment. The maximum practical ZC/F ratio is estimated at 0.4, which is obtained with a 50-ohm cable, a capacitance of 3,200 micromicrofarads, and a front of 0.4 microsecond. The minimum ZC/F ratio will be very close to zero. A study of Figure 5 will show that the surge voltage at the equipment will not vary more than ±3 per cent as the ZC/F ratio varies between zero and 0.4, which indicates that it is not essential to have exact data on the terminating capacitance. It is suggested that protection practices be based on a capacitance of zero or 3,200 micromicrofarads, depending on which value gives the most severe voltage at the terminal equipment.

The cable surge impedance Z appears

Table V. Surge Impedance of Cables

Conductor Size, Thousand Circular Mils	Voltage Class, Kv 4–5	7–8	14–15	22–23	34–35
83.69	14.4	19.6	25.6	30.5	
133.1	12.0	16.6	21.8	26.3	32.8

[2] Average discharge voltage at 10,000 amperes, plus full positive tolerance.

in the ZC product, as discussed before, and also influences the magnitude of the front F. It will be recalled that the front F was defined as the ratio of the maximum voltage to the rate-of-rise of voltage at the junction pothead. Assuming a current surge having a rate-of-rise of K kiloamperes per microsecond coming in over the overhead circuit, the rate-of-rise of voltage at the junction pothead is $2Z_1ZK/(Z_1+Z)$. The overhead-circuit surge impedance Z_1 appears in both the numerator and denominator, and is large by comparison to the cable surge impedance, so practical variations in this impedance will have only a small influence on the rate-of-rise of voltage at the junction pothead. The use of a typical value of 500 ohms should, therefore, be satisfactory. The cable surge impedance, however, has considerable influence on the rate-of-rise of voltage at the pothead, and consequently on the front F, so should be retained as a variable. Typical values are included in Table V.

Surge Currents. The front F is a function of the maximum voltage and the maximum rate-of-rise of voltage across the junction pothead, and, therefore, depends on the magnitude and rate-of-rise of the surge currents reaching the junction between the overhead circuit and the cable. Surges originating at some distance will be limited in magnitude by the overhead-line insulation level and surge impedance. Assuming a line level of 1,000 kv, which is probably higher than used on low-voltage circuits, even with woodpole construction and no down leads, the maximum current in an incoming surge is limited to less than 2,000 amperes. Considering reflections, the lightning-arrester current might approach twice this value, or 4,000 amperes. If low-voltage circuits were protected with properly designed shielding, it would be considered adequate to base equipment protection on lightning-arrester currents of this order of magnitude. However, as shielding is not generally used over the lower voltage lines, consideration should be given to close-in strokes to the line conductors. For such strokes, the struck point may be protected from flashover by reflections from the cable, in which case the lightning-arrester current may approach the stroke current.

The distance over which these reflections can protect the line insulation depends on the rate-of-rise of stroke current and on the line insulation level. Assuming a rate-of-rise of current of 4,000 amperes per microsecond, which might correspond to a 10,000-ampere stroke with a $2^1/_2$ microsecond front, the voltage at the struck point will rise at 1,000 kv per microsecond, assuming a 500-ohm line. If the line insulation level to ground is 500 kv at this rate-of-rise, reflections must return from the cable in 0.5 microsecond to prevent flashover, which means the struck point must be within 250 feet of the cable junction. The probability of exceeding 10,000 amperes in a stroke is 50 strokes per 100 miles per year,[3] or one stroke in 40 years to a 250-foot line section. If protection were based on a 10,000-ampere stroke with a $2^1/_2$-microsecond front, the protection limit would be exceeded on an average of once in 40 years. This, however, does not mean that apparatus failures would result this often because probable lightning-arrester characteristics and equipment margins, which were not considered, enter into the overall probability picture.

The data in Table VI show the influence of line insulation level on the protection afforded if such protection is based on the stroke currents given in the table. These results are based on a stroke current having a $2^1/_2$-microsecond front, which is probably on the conservative side. It is evident that the line insulation level is a primary factor in the surge protection of cable-connected equipment. In any particular application, where the line insulation level is known, it is possible to select a lightning-arrester current for co-ordination purposes and estimate the probability of exceeding this current. However, for general application purposes it would be highly desirable to simplify procedures by basing all excepting special cases on the same lightning-arrester current. With this in mind, the authors have tentatively selected a current having a magnitude of 10,000 amperes and a rate-of-rise of 4,000 amperes per microsecond. The calculated results in Table VI indicate that this protection limit might be exceeded once in 40 years if the line insulation level is as high as 500 kv to ground. Field studies show that approximately 0.8 per cent of the current discharges in station lightning arresters might exceed 10,000 amperes.[3] By comparison to the 4,000 amperes per microsecond rate-of-rise, the highest rate ever recorded in an arrester was between 5,000 and 5,500 amperes per microsecond.[4]

Lightning Arrester Characteristics. The published information on valve-type lightning arresters includes average impulse sparkover and discharge voltages, and permissible tolerances. Only a small percentage of the lightning arresters manufactured will have positive tolerances exceeding one-half the permissible maximum values. For this reason the authors have chosen to base protection of cable-connected equipment on lightning-arrester characteristics equal to the average published values plus one-half the permissible positive tolerances. The only exception is the discharge voltage of distribution lightning arresters, in which case the maximum tolerance is used. This exception is made because all manufacturers do not design to the same average discharge voltage in these lightning arresters, and consequently a larger percentage of these lightning arresters may

Table VIII. Maximum Lead Drops Assumed in Tables II and III

have discharge characteristics exceeding those that would be obtained if only one-half the permissible tolerance were used. The maximum lightning-arrester voltages used for co-ordination purposes are given in Table VII for ratings up to 37 kv. These are based on the lightning-arrester discharge voltages at 10,000 amperes, including tolerances as discussed above.

Lightning Arrester Leads. Careful consideration should be given to the length of lightning arrester leads because approximately 1.6 kv will appear across each foot of lead at discharge currents of 4,000 amperes per microsecond. The voltages given in Table VIII have been assumed for general co-ordination purposes and are based on an inductance of 0.4 microhenry per foot of lead and a current rate-of-rise of 4,000 amperes per microsecond. The lead lengths required to produce these voltages also are included. The general data in this paper permit an evaluation of the protection afforded in those applications where the lead lengths differ from those in Table VIII.

Evaluating the Front F. Having established the maximum voltage across the junction pothead, which is the lightning-arrester voltage plus lead drop, it is next necessary to determine the maximum rate-of-rise of voltage across the pothead to evaluate the front F. As given in a previous section, the rate-of-rise of voltage is equal to $2Z_1ZK/(Z_1+Z)$, where Z_1 and Z are the overhead line and cable impedances, and K is the rate-of-rise, in kiloamperes per microsecond, of the incoming surge. The front F, in microseconds, is then obtained by dividing the total junction pothead voltage by the rate-of-rise of pothead voltage.

For general application purposes, the authors have assumed a current with a 4,000-ampere-per-microsecond front entering the cable. This rate-of-rise multiplied by the maximum cable surge impedance expected in any voltage class gives the rates of voltage rise in Table IX.

Illustrative Example. To illustrate the application of the basic data included in Figure V, a typical case will be reviewed in detail. In this example the following conditions are assumed:

200-foot 15-kv power cable with a surge impedance of 25 ohms.

Voltage at terminal equipment to be limited to 95 kv.

Terminal equipment capacitance = 1,000 micromicrofarads.

Lightning-arrester lead length = 3 feet.

Protection to be based on a surge current with 10,000 ampere-magnitude and 4,000-amperes-per-microsecond rate-of-rise.

The lowest voltage lightning arrester normally used with 95-kv equipment is the 12-kv unit. Assuming a 12-kv station-type lightning arrester, the maximum lightning-arrester voltage is 47 kv as given in Table VII. Based on 0.4 microhenry per foot, the lead drop is 4.8 kv, giving a total voltage of 51.8 kv across the junction pothead.

The maximum rate of rise of voltage across the junction pothead is equal to 100 kv per microsecond, which is based on a 4,000-ampere-per-microsecond surge into a 25-ohm cable.

$$\text{Front } F = \frac{51.8}{100} = 0.518 \text{ microsecond}$$

$s = 200$ feet

$s/v = 200/500 = 0.4$ microsecond

$$\frac{s/v}{F} = 0.4/0.518 = 0.771$$

$$\frac{ZC}{F} = \frac{25 \times 1{,}000}{0.518} \times 10^{-6} = 0.0483$$

From Figure 5

$E_r/E_a = 1.96$

$E_r = 1.96E_a = 1.96 \times 51.8 = 102$ kv

As this voltage exceeds the permissible voltage of 95 kv, the protection is inadequate. Protection cannot be provided for a 10,000-ampere 4,000-ampere-per-microsecond surge without additional lightning arresters at the equipment. If the terminal apparatus were in Class II, having a 95-kv full-wave level and a 110-kv chopped-wave level, the protection would be considered adequate without additional lightning arresters at the equipment.

General Studies

This part of the paper discusses in some detail the impulse laboratory and analogue computer studies made to obtain the basic data used in formulating the application guides in the first part of the paper. In general, the procedure consisted of making tests in the Impulse Laboratory on 15-kv power cable, and then using these data to show that satisfactory

results could be obtained by making the general studies on the analogue computer.

Impulse Laboratory Tests

In order to obtain fundamental data on the propagation of surge voltages through cables, a series of tests was conducted in the Impulse Laboratory on 200- and 1,000-foot lengths of 15-kv 2/0 single-conductor lead-covered cable. In making the tests the cable was removed from the reel and looped back and forth on the dry concrete floor in the laboratory. This precaution was taken to rule out the possibility of extraneous effects due to contact or capacitance between adjacent turns on a reel. The two ends of the cable were brought to a common point and the lead sheath bonded to the surge generator ground. Steps were taken to keep terminal lead lengths as short as physically possible. The general arrangement of the laboratory circuits is illustrated in Figure 6. Tests were made with an applied wave having a sustained tail and also with an applied wave, chopped on the front. The sustained-tail tests were made by discharging the surge generator into a 3-kv station-type lightning arrester block connected conductor-to-sheath at one end of the cable. The front was controlled by inductance in series with the surge generator. In making the chopped-wave tests, the lightning arrester block was replaced by a sphere gap, and the front controlled with resistance in parallel with the gap, and resistance and inductance in series with the generator.

Six records were taken at each end of the cable for each test condition, primarily to show that consistent records were being obtained.

Table X summarizes the results of the tests made with an applied voltage having a sustained tail. Terminating capacitance values up to 6,300 micromicrofarads were used with both cable lengths. The maximum value of the applied surge is given in kilovolts, and the crest receiving- or remote-end voltage is expressed as a ratio to the applied voltage. The receiving-end voltages generally fall between 1.83 and 1.93 times the applied voltage for the 1,000-foot cable, the results being substantially independent of the wave front and the terminating capacitance. The voltages recorded in the 200-foot-cable tests range between 1.87 and 1.98, the highest value being obtained with a 6,300-micromicrofarad terminating capacitance. The tests do show that the receiving-end voltages approach, within about 5 per cent, the theoretical figure of 2.0 for an open-end cable without loss, indicating that attenuation is not a primary factor in cable lengths up to 1,000 feet. It also is apparent that attenuation does not increase directly with cable length.

The oscillograms in Figure 7 are typical records obtained in the tests made with an applied surge having a sustained tail. Oscillogram 88 shows the receiving-end voltage for the case of a 0.5-microsecond-front wave applied to a 200-foot cable, open circuited at the receiving end. The maximum receiving-end voltage is approximately 191 per cent of the crest value of the applied voltage. Oscillogram 82 shows a receiving-end voltage of 193 per cent for the same surge applied to a 1,000-foot cable, open circuited at the receiving end. These data show that attenuation factors obtained from tests on one cable length cannot be used to calculate attenuation in other cable lengths. If attenuation were directly proportional to cable length, the over-voltage recorded on a 1,000-foot cable would have been considerably lower than on a 200-foot cable. The fact that the recorded voltage is higher on the longer cable is not

Figure 9. Plot of transient components of surge voltages from oscillograms 62, 88, and 99 of Figure 7

significant because the difference is less than the accuracy expected in reading the oscillograms.

An inspection of oscillogram 82, Figure 7, shows that attenuation is much larger on the front than on the tail of the wave. On the front, when the rate-of-change of current in the cable is high, the current penetration into the surface of the copper and lead is very small, resulting in a large effective resistance. The lower rate-of-change of current on the tail permits a deeper current penetration and a lower effective resistance. It will be noted, however, that there is no abrupt change in attenuation because time is required for the current to redistribute in the conductors. Shunt losses will also be higher on the front when the rate-of-change of voltage across the cable insulation is a maximum. These factors make the analytical determination of attenuation extremely difficult.

Oscillogram 62, Figure 7, was recorded on a 1,000-foot open-end cable with the front of the applied surge increased to 1.1 microseconds. Several cycles of the oscillation are included to show the general attenuation of the open-end voltage. The maximum receiving-end voltage is 193 per cent of the applied voltage, which is the same as recorded with a 0.5 microsecond-front applied surge. This shows that, within limits, the front has little influence on the maximum voltage. This condition should hold for fronts as long as twice the cable propagation time.

In obtaining oscillogram 99, Figure 7, the 200-foot cable was terminated in a 6,300-micromicrofarad capacitor. The receiving-end voltage was 198 per cent as compared with 191 per cent recorded without the capacitor termination, indicating that the maximum voltages are not obtained with open-end cables. In order to obtain a better picture of the influence of capacitance, a 1,000-foot cable was terminated in a 14,300 micromicrofarad capacitor. The receiving-end voltage in Figure 8 shows an increase in voltage, or pip, just before the voltage decreases to zero. This pip is present because the reflection from the receiving end of the cable is negative until the capacitor is charged to a potential equal to the magnitude of the incoming surge, after which the reflection is positive. The negative reflection from the receiving end reflects as a positive voltage from the sending end of the cable, because the voltage at that point is maintained. It then adds to the receiving-end voltage. The maximum voltage actually recorded was only 192 per cent because the sending-end voltage was not maintained at a constant level. Estimates indicate that the voltage would have been around 210 per cent if the sending-end voltage had been maintained at its maximum value.

Table XI is a summary of the data obtained with chopped waves applied to the test cable. In this case the receiving-end voltages are influenced considerably by the front of the applied voltage. With the 1,000-foot cable the voltages vary between 1.46 and 1.94 as the front is changed from 0.45 to 3.5 microseconds. The voltages recorded with the longer fronts do not differ significantly from the maximum voltages measured with an applied wave having a sustained tail. Adding capacitance at the receiving end definitely reduces the voltages. Tests 113-26 were made with an applied surge having a front considerably longer than twice the cable propagation time, which accounts for the low voltages recorded. In these cases the receiving-end voltage is chopped by reflections before the voltage has a chance to build up to twice the incoming surge. With chopped waves the attenuation is more nearly proportional to cable length, which was not the case with applied voltages having sustained tails.

The oscillograms in Figure 7 are typical of the ones obtained in the chopped-wave tests. Oscillogram 104 applies for the case of a 0.7-microsecond-front surge applied to a 200-foot open-end cable. The receiving-end voltage was equal to 1.97 times the crest of the applied voltage. Terminating the same cable with a 6,300-micromicrofarad capacitor decreased the voltage to 1.57 (see oscillogram 110). Oscillograms 35 and 45 show the voltage at the receiving end of a 1,000-foot cable with applied voltages having fronts of 0.5 and 3.5 microseconds, respectively.

Table XII. Comparison Between Measured and Calculated Resistance

Condition	Measured Resistance, Ohms*	Calculated Resistance, Ohms
200-foot open-end cable	3.72	2.06
200-foot cable terminated in 6,300-micromicrofarad capacitor	2.24	1.67
1,000-foot open-end cable	3.47	3.03

* Resistance obtained from decrement of surge voltage recorded in Impulse Laboratory cable tests.

Losses. The general shape of the voltage in oscillogram 88, Figure 7, indicates that the receiving-end voltage might be approximated by a steady-state component equal to the applied voltage, and a transient component that decays exponentially with time. This representation, although not strictly correct, furnishes a method of estimating attenuation analytically. Figure 9 is a plot of the transient components obtained from oscillograms 62, 88, and 99. In these plots the voltage is expressed in per cent of the magnitude of the transient component at the instant of the maximum receiving-end voltage. Time is measured from the instant of maximum receiving-end voltage. It will be noted that the plotted points fall very close to straight lines indicating that the decrement can be approximated by the use of the simple resistance-inductance-capacitance circuit damping factor $\epsilon^{-Rt/2L}$. The inductance of the test cable was estimated at 9.93 microhenries per 200 feet. Using this inductance and the data from oscillogram 88, Figure 7, the effective cable resistance is estimated at 3.72 ohms per 200 feet. An effective resistance of 2.24 ohms was estimated for the case involving the 6,300-micromicrofarad terminating capacitance, indicating that capacitance has some influence on loss. The estimated resistance for the 1,000-foot open-end cable is 3.47 ohms, which is actually less than the effective resistance of the 200-foot open-end cable.

Figure 11. Calculated $2L/R$ ratios for oil-impregnated paper-insulated, single-conductor power cables

Figure 13. Voltage at the end of a 200-foot cable terminated in a capacitor

A. Calculated without attenuation. B. Analogue computer data
C. Impulse Laboratory data

As a basis for checking the effective resistances obtained from an analysis of the oscillographic data, a method was developed for estimating loss from the cable characteristics. The cable power factor was measured over a frequency range of 950 kc as shown in Figure 10. Also, included are test points obtained in measurements on an oil-insulated capacitor unit.[8] The close agreement between the cable and capacitor test data illustrates that the power factor is a function of the insulating materials only.

Knowing the cable capacitance and power factor, it is possible to determine the effective shunt resistance of the cable at any frequency. This shunt resistance can be converted to an equivalent series resistance, as follows:

$$\text{Loss} = i^2R(\text{series}) = \frac{e^2}{R(\text{shunt})}$$

$$R(\text{series}) = \frac{e^2}{i^2R(\text{shunt})} = \frac{Z^2}{R(\text{shunt})}$$

where

Z = cable surge impedance

This relation between shunt resistance and equivalent series resistance can be considered approximate only when dealing with traveling waves, because voltage and current are not always related by surge impedance at all times and locations in the cable. The relation has been retained, however, because no better practical method has been developed for introducing attenuation due to dielectric loss.

The series resistance of the conductor and lead sheath are calculated, at the desired frequencies and added to the equivalent series resistance, used to represent shunt loss. Following this method, the effective resistances given in Table XII were calculated for the cases discussed previously. The measured losses are higher than the calculated values, which is partially explained by the more rapid attenuation of the higher-frequency components in the measured voltages, and by reflection losses present because the applied voltage was not held exactly constant. Both the measured and calculated values show that the effective resistances are influenced by terminal capacitance and by cable length.

As a basis for estimating attenuation in single-conductor cables, the $2L/R$ ratios in Figure 11 were calculated for cables in voltage classes between 4 to 5 and 34 to 35 kv. In making the necessary calculations, it was noted that conductor size had little influence on the ratios. Small conductors had large series losses and low shunt losses, whereas the large conductors had small series losses and large shunt losses, the $2L/R$ ratios being substantially independent of conductor size.

In using these ratios for estimating

Figure 12. Calculated receiving-end to sending-end voltage ratios for open-end cables

purposes, the lowest natural frequency of the circuit is obtained, including the effects of terminal capacitance. The data in Figure 17 can be used for this purpose. The $2L/R$ ratio corresponding to this frequency and the cable insulation class is then used in the damping factor relation $\epsilon^{-Rt/2L}$. Figure 12 is a plot of the calculated receiving-end to sending-end voltage ratios for cable lengths from 100 to 6,000 feet, including the effects of attenuation. These curves apply for the case of open-end cables, that is, no terminating capacitance, and assume the front of the junction-pothead voltage is less than twice the cable propagation time. These curves are included to show the probable trend of the voltage ratios with cable length and cable insulation class.

Comparison of Anacom and Impulse Laboratory Test Results

Three receiving-end voltage curves are plotted in Figure 13, all applying to the case of a sustained-tail wave applied to a 200-foot cable terminated in a 6,300-micromicrofarad capacitor. The highest voltage shown was calculated and neglects all attenuation. The analogue computer curve was obtained with a 20-*pi* section representation of the cable, and includes the effects of the inherent loss of the computer elements. The Impulse Laboratory curve includes the actual loss in the 15-kv power cable. These results show that the analogue computer and Impulse Laboratory test results check very closely over the first 1.6 microseconds.

The curves in Figure 14 apply for the same case, and compare the analogue computer and Impulse Laboratory re-

Figure 14. Surge voltage at the end of a 200-foot cable

Solid curve—Analogue computer data
Dashed curve—Impulse Laboratory data
Cross—Analogue computer data, including calculated attenuation

sults over a period of four microseconds. It will be noted that the Impulse Laboratory curve is considerably below the analogue computer curve at the time of the second peak, which is attributed to the lower attenuation in the analogue computer circuits. The cross in Figure 14 represents the second crest obtained by applying attenuation to the first crest of the computer curve. Attenuation was applied on a straight time basis using the simple resistance-inductance-capacitance circuit decrement factor $\epsilon^{-Rt/2L}$. These results indicate that reasonably satisfactory results can be obtained by applying calculated decrement to the analogue computer data, whenever it is necessary to know the general shape of the entire receiving-end voltage curve. It would be possible to include decrement in the computer studies; however, this would require a separate study for each voltage-class cable. Furthermore, it is the authors' opinion that accurate data are not generally required on the magnitude of the second and successive peak voltages.

Figure 15 compares analogue computer and Impulse Laboratory data for a case involving a 1,000-foot cable terminated in a 2,000-micromicrofarad capacitor. The significant difference between these two curves is the rapid rise to maximum voltage as obtained on the analogue computer and the more gradual rise obtained in the Impulse Laboratory. This difference is due to the high losses present in a cable when the applied surge has a short front, and the gradual change to a condition of low loss on the tail. This characteristic of the cable, which was not represented on the analogue computer, is not significant in applications where it is necessary to limit the maximum voltage, irrespective of wave shape, to a prescribed level. However, in applications involving oil-insulated equipment, where it should be possible to take advantage of higher short-time insulation levels, the actual shape of the voltage curves may prove to be important.

Analogue Computer Studies

After it was established that satisfactory agreement could be obtained between analogue computer studies and Impulse Laboratory tests, a general investigation was made on the computer. The analogue of the cable consisted of *pi* sections as shown in Figure 16, a total of 20 being used for cables up to 800 feet in length. An appropriate time base was selected to keep the natural frequencies of the computer circuits within desirable limits, so that the losses would not exceed those expected in an actual power cable. The complete analogue depended upon the ratio of the cable propagation time to the front F. The circuit in Figure 16(A) was used for those cases where this ratio was more than 0.5. The capacitor C_1 is charged through resistor R_1 by closing switch S_1. When the voltage across C_1 reaches the desired level, switch S_2 is closed to hold the voltage across C_1 constant. The battery voltage is large by comparison to the maximum cable-input voltage in order to produce a relatively uniform rate-of-rise of voltage. The capacitance C_1 is large in order to prevent reflections from changing the input voltage appreciably. With this analogue the voltage across the input end of the cable has the wave shape illustrated in Figure 2(B).

The analogue in Figure 16(B) was employed in those cases where the ratio of cable propagation time to the front F was

Figure 15. Surge voltage at the end of a 1,000-foot cable

A. Analogue computer data
B. Impulse Laboratory data

less than 0.5. Capacitor C_1 is charged through resistor R_1 by closing switch S_1. The voltage across C_1 is applied to the cable-input terminals through resistor R_2, which represents the overhead line surge impedance. When the voltage across the cable terminals reaches the desired level, switch S_2 is closed to hold the voltage constant. Capacitor C_2 is large enough to prevent reflections from altering the voltage established by battery V_2. It should be noted that, with this analogue, reflections from the remote end of the cable can influence the voltage across the cable-input terminals until switch S_2 is closed.

The computer studies were based on a 25-ohm cable and terminating capacitance values from zero to 12,800 micromicrofarads. A front F of 0.4 microsecond was represented in all cases. The cable length was varied between 25 and 800 feet.

In selecting these limits, it was realized that the basic variables in the problem were the surge propagation time of the cable, the duration of the front F, and the time constant of the circuit consisting of the cable surge impedance and the terminating capacitance C. As all of these basic variables can be expressed

Figure 16. Basic circuits used in analogue computer studies

Figure 17. Typical oscillograms obtained in analogue computer studies

in microseconds, generalization of the computer data is possible.

Let:

s = cable length in feet

v = velocity of surge protection in the cable in feet per microsecond

Z = cable surge impedance in ohms

C = terminating capacitance (effective capacitance of terminating equipment) in microfarads

F = front in microseconds of the voltage across the cable input terminals, neglecting reflections

Then

s/v = cable propagation time in microseconds

ZC = time constant in microseconds of the circuit consisting of the cable and terminating equipment

If the cable propagation time and the circuit time constant are divided by the front F, these two quantities will be expressed in per unit, where one per unit time is the length of the front F. They also may be expressed as ratios to the front, obtaining the ratios $(s/v)/F$ and ZC/F. These two ratios are, in effect, the only two fundamental variables involved. Reducing the five variables encountered in cable applications to two fundamental variables permits generalization of the computer data obtained with a 0.4-microsecond front and a 25-ohm cable.

General Data. Typical oscillograms obtained in the computer studies are shown in Figure 17. The upper line of oscillograms is the voltage across the input terminals of the cable, neglecting reflections from the remote end. In each case this voltage rises to 100 per cent in 0.4 microsecond. As reflections do not alter the input voltage when the $(s/v)/F$ ratio is greater than 0.5, based on the assumptions made in this study, the upper line of oscillograms is also the actual voltage across the cable-input terminals for $(s/v)/F$ ratios of 0.5, 1.0, and 2.0. The input voltages, as modified by reflections, are shown in Figure 18 for $(s/v)/F$ ratios of 0.125 and 0.25.

The second line of oscillograms in Figure 17 shows the voltage across the remote end of the cable for the case of zero terminating capacitance. The succeeding lines illustrate the general shape of the receiving-end voltages with ZC/F ratios up to 0.8.

Adding capacitance to the remote end of the cable has a tendency to decrease the maximum voltages for $(s/v)/F$ ratios below 0.5 and to increase the voltages for the larger ratios. It should be noted that the maximum voltage exceeds 200 per cent for some of the cases, the voltage above 200 per cent appearing as a short-duration pip. These pips are more pronounced in these studies than in the Impulse Laboratory studies, indicating that they suffer high attenuation in an actual cable. As practical ZC/F ratios will be less than 0.4, these pips are not too significant in the over-all protection problem.

The lines in Figure 17 are labeled in terms of ZC/F ratios, and also ZC products based on a 0.4-microsecond front. The column headings include $(s/v)/F$ ratios, and also cable length in feet based on a 0.4-microsecond front and a velocity of propagation of 500 feet per microsecond. The upper figure of the individual records is the maximum voltage expressed in per cent of the input voltage. The figure in parentheses is the time to maximum voltage in microseconds, assuming a 0.4-microsecond front and velocity of propagation of 500 feet per microsecond. For other fronts these times will vary directly with the front.

Figure 5 summarizes the maximum receiving-end voltages obtained in the computer studies. The voltages are expressed as ratios to the maximum voltage at the sending or input-end of the cable.

Integration Method

In the integration method of evaluating the effect of surge voltages on oil-insulated transformers, the disruptive effect of the surge is defined by the equation

$$DE = \int (e - K_1)^{K_2}\, dt,$$

where

DE = disruptive effect

e = volt-time curve of the applied surge

K_1, K_2 = constants fixed by the standard transformer test voltages

This relation was established on the general basis that transformer insulation could withstand some constant voltage K_1 for an extended period of time (a few hundred microseconds) without suffering ill effects. It was realized that the disruptive effect of a surge is a function of both voltage magnitude and time, but that these two factors are not of equal importance. Introducing the exponent K_2 allows some variation in the relative weight given to magnitude and time. The constants in the disruptive-effect equation can be evaluated from the standard tests for transformers, if the assumption is made that the tests are of equal sever-

Table XIII. Constants Used in Integration Equation

Insulation Class, Kv	Basic Insulation Level, Kv	K_1	K_2	Disruptive Effect
5.0	75	73.5	0.579	1.27
8.66	95	90.5	0.997	8.34
15.0	110	98.8	1.808	3.6×10^{9}
23.0	150	46.5	6.75	2.78×10^{14}
34.5	200	90.0	5.65	2.90×10^{13}

Solid curves—integration method
Dashed curves—voltages limited to chopped-wave level

ity. This assumption should be reasonable from a general application standpoint because transformers must be designed and built to withstand these standard tests. The general form of the equation requires that the constants be evaluated by a cut-and-try procedure. The constants have been evaluated for insulation classes up to and including 34.5 kv, and are given in Table XIII. The disruptive effect, obtained by substituting any one of the three standard test waves in the equation, is also included in the table.

As the equation gives the same disruptive effect for the three standard test waves, which vary over a wide range in magnitude and duration, it should give acceptable accuracies in determining whether particular nonstandard waves are more, or less, severe than the standard test waves. Judgment, however, is required in evaluating oscillatory waves as experienced on circuits involving transformers connected to overhead lines through cable. The authors have integrated only the first cycle of such oscillations, because the second cycle is usually of appreciably reduced magnitude, and because the condition of the insulation probably improves some during the period of low voltage between the first and second crests of the oscillation.

Figure 19 is a comparison of the permissible junction pothead voltages for Class II equipments for two methods of interpretation of the basic data. The dashed curves are based on limiting the surge voltages to the equipment chopped-wave levels, and the solid curves are based on the integration method. It should be noted that the solid curves are based on a front F of 0.4 microsecond, rather than on a surge current having a 4,000-ampere-per-microsecond rate-of-rise. Assuming a constant front of 0.4 microsecond makes these curves somewhat more conservative, especially with the shorter cables.

The integration method permits higher voltages with short cables, and slightly lower voltages with the longer cables. This should be expected because the times associated with the overvoltages with short cables are less than the minimum times to flashover used in chopped-wave testing, whereas with long cables the reverse is true. The curves would indicate that the equipment voltages should be held below the chopped-wave levels with the longer cables. Practical considerations, however, will show that this requirement is not necessary. First, the differences even with 1,000-foot cables are only 7 per cent. Second, the analogue computer studies were based on the assumption that the maximum junction-pothead voltage is maintained for twice the cable propagation time, which is 4 microseconds in the case of a 1,000-foot cable. The probability of this happening in an installation not having adequate equipment-insulation margin is considered too small to be a significant factor.

Although the integration method indicates that the surge voltages at the equipment may be permitted to exceed the chopped-wave levels, the authors decided not to take advantage of this possibility at this time. It was felt that further study should be given to the influence of wave shape on the permissible maximum voltages before co-ordinating with anything higher than the chopped-wave levels.

Discussion

P. A. Abetti (General Electric Company, Pittsfield, Mass.): This discussion is concerned with the representation of transformers at the cable terminal.

While the authors have gone into a detailed investigation of the effect of the losses in the cable, they have neglected completely the losses in the terminal equipment. In particular, transformers have been represented as pure capacitances, thereby neglecting the damping of the oscillations due to the losses in the transformer winding, and in the capacitances to ground, to shield, between coils, and between turns. These losses may be considerable at high frequencies. Especially for short cable lengths, these internal losses of the transformer, rather than the cable losses, are instrumental in limiting the maximum voltages at the transformer terminals.

This statement is corroborated by Figure 10 of the paper, where it is shown that cable insulation and capacitor insulation have the same power factor. It is believed that the losses are larger in a transformer than in a commercial capacitor, and it would be interesting to know whether the authors have any such data taken on transformers, and whether they have made tests to determine the reduction of the terminal voltage due to this factor.

W. L. Teague and **L. B. Rademacher** (Westinghouse Electric Corporation, Sharon, Pa.): The paper presents pertinent data in a very useful and concise form. By using Table II and III of the paper, the maximum cable length permissible for general applications is given directly. For more specific applications, the curves, Figures 3 and 4 of the paper, and the basic application data permit a more detailed study. The tables and figures mentioned above are derived from Figure 5 of the paper which contains the basic data for the complete investigation.

During 1947 and 1948 a similar investigation was made at Sharon and the data obtained, Figure 1 of the discussion, are superimposed on Figure 5 of the paper. For this study either an actual transformer or a simulated transformer and a 37-ohm cable were used to give a ZC/F value of 0.195. By starting with a 200-foot cable and cutting to the desired length, the length was varied from 200 to 50 feet. Initially the tests were made using several ratings of completely assembled lightning arresters and the 200-foot cable. The action of the lightning-arrester isolating gap caused erratic fronts which made interpretation difficult. Like the authors tests, the isolating gaps were removed and the major part of the study was made without the lightning arrester gap. The data presented in Figure 1 of the discussion are for the gap removed.

Over a $(s/v)/F$ factor of 0.25 the two sets of data are in good agreement. Below this value, Sharon's data show a lower reflection ratio (E_R/E_S) for corresponding values. This difference is attributed to the omission of the lightning arrester isolating gap. Theoretically, this error should occur at 0.5 and become predominately greater as the ratio decreases. With the isolating gap in lightning arrester and for $(s/v)/F$ values between 0.125 and 0.5 the initial reflected wave from the transformer e_1 sees at the junction of cable, overhead line, and lightning arrester the high impedance of the overhead line and the low capacitance of the lightning arrester isolating gap; capacitance only at the lightning arrester since it has not operated as yet. At this point because of high-surge impedance of the overhead line and the relatively low impedance of the cable, a positive reflected wave having approximately the same magnitude and wave front as e_1 is reflected back to the transformer. It is this reflected wave that reaches the transformer before the lightning arrester operates that causes the higher reflection ratio as reported by Mr. Witzke and Mr. Bliss.

In the case for no isolating gap, the reflected wave from the transformer e_1 sees at the junction point the low impedance of the lightning arrester block limiting the total voltage, lightning arrester voltage plus e_1, to just the lightning arrester discharge voltage. This action will send a negative reflected wave back to the transformer. This negative wave added to the original traveling wave causes a lower voltage at the transformer, and thus a lower reflection ratio as shown by our data.

For smaller $(s/v)/F$ values the same arguments can be applied. It is evident how more reflections will occur with the smaller $(s/v)/F$ values for the isolating gap case and thus produce a larger reflection ratio. The valid range for the various approximate equations for calculating the reflection ratio are given as

$$\frac{E_R}{E_S}=\frac{4}{3}\left(1+\frac{s/v}{F}\right)0.5\geq\frac{s/v}{F}\geq0.125 \qquad (1)$$

$$\frac{E_R}{E_S}=\frac{6}{5}\left(1+\frac{2s/v}{F}\right)0.125\geq\frac{s/v}{F}\geq0.056 \qquad (2)$$

$$\frac{E_R}{E_S}=\frac{8}{7}\left(1+\frac{3s/v}{F}\right)0.056\geq s/v\geq0.0315 \qquad (3)$$

By using equations 1, 2, and 3 it can be seen that Witzke's and Bliss' data below 0.25 are correct. Above this value the two sets of data agree, which is most gratifying since the two investigations were carried out independently and in different laboratories. The agreement of the data also shows the value of the analogue computer which is much easier and less time-consuming to use provided the actual circuit constants are known.

From the paper it should be apparent that for cable-connected equipment careful consideration should be given to proper surge protection. It also points out that the practice of installing lightning arresters at the junction between overhead lines and cable is sound for many applications.

H. A. Cornelius (Public Service Company of Northern Illinois, Chicago, Ill.): Evaluation of many factors which must be considered in the problem of providing satisfactory lightning protection for cable-connected electric equipment has been needed in the industry for a long time. The paper by Mr. Witzke and Bliss is considered a major contribution which will be of great value to protection engineers and to the industry at large.

With the Witzke and Bliss data available, it will be possible to make lightning-arrester applications with greater assurance that the results will be satisfactory, than has been possible in the past.

A. M. Opsahl (Westinghouse Electric Corporation, East Pittsburgh, Pa.): For years the hazards of double voltage reflections at the ends of cables tied to overhead lines have been pointed out. Witzke and Bliss have made a very adequate study of the problem and have assigned very definite values to the factors involved.

Flashovers do occur at the ends of cables, but no extensive surveys have been made to evaluate the percentage of trouble. The authors express the estimated hazard in terms of the average number of years per outage at a given location. One outage in 40 years at a given location seems safe, but expressed in another way, one flashover in 40 installations, even with the recom-

Figure 1. Maximum receiving-end voltages expressed as a ratio to the maximum sending-end voltage. Sharon data superimposed on Figure 5 of the paper

Figure 2. Top oscillogram shows the discharge through a single set of pole-mounted lightning arresters. In the lower oscillograms the discharge duty is shared by the pole and switchgear lightning arresters

mended protection may not seem so safe. There are alleviating circumstances however. The second cable connected to the same terminal equipment in many installations eliminates the over-voltage reflection. Cable entrances would be more common in the densely-populated areas where lightning exposure of the line is low, and there may be lightning arresters on the line near the cable entrance. Slower rates of rise of surge voltage and current than those in the study will decrease the magnitude of the reflections on the shorter cables. As opposed to these alleviating conditions, the older installations will have questionable co-ordination between insulation and the lightning-arrester protective characteristic. Lightning-arrester ground leads at the line end of cable may not be tied to the cable sheath at the top of the poles as is assumed and recommended in the study.

Nonmetallic-sheath cable has no sheath to tie to the lightning-arrester ground lead, and its insulation will be subjected to all of the lightning-arrester discharge voltage plus impedance drop in the lightning arrester ground circuit. The nonmetallic-sheath cable is more nearly like a section of overhead line with much reduced insulation. Lightning protection of the equipment at the end of overhead lines is the object of an additional study.

H. B. Wortman (Westinghouse Electric Corporation, East Pittsburgh, Pa.): This paper provides, in an easily usable form, the information for properly applying surge protection to cable-connected equipment. While it had been accepted that the length of the connecting cable was a factor, there was little quantitative data available. The tables showing the combinations of lightning arresters and connected cable lengths and formulas for the calculation of surge behavior for a given set of conditions will be very helpful.

There has been an increasing interest in the need for lightning-arrester protection of individual circuits. The information contained in this paper will determine the amplitude of the surge voltage possible at the switchgear end of the circuit. If this exceeds the basic insulation level rating, then consideration should be given to the capacity of the switchgear lightning arresters.

Since the switchgear lightning arresters share the discharge burden with the pole-mounted lightning arresters, the distribution type will usually provide adequate capacity. Figure 2 of the discussion shows a test circuit and oscillograms illustrating the result of this parallel discharge circuit.

To obtain this data, a 200-foot length of lead-covered cable was connected to a metal-clad unit. In the first test and oscillogram, a lightning arrester was connected to the cable end away from the switchgear. This simulated the usual pole-mounted lightning arrester. The current through this single lightning arrester reached a maximum of 4,750 amperes.

The lower set of oscillograms shows how the discharge was shared when a lightning arrester was added to the switchgear end of the cable. In this case, the maximum current through what would be the pole-mounted lightning arrester was 3,480 amperes, while the current through the switchgear lightning arrester was 1,220 amperes, only about 25 per cent of the total.

The fact that most of the discharge duty is assumed by the pole-mounted lightning arrester makes the use of the distribution-type generally satisfactory for switchgear protection.

This paper will serve as a guide to more complete protection of metal-clad switchgear connected to overhead lines. If lightning arresters are necessary, adequate and more economical protection can usually be obtained through the use of distribution-type lightning arresters. In cases when more discharge capacity is needed, station-type lightning arresters should, of course, be used.

E. M. Hunter (General Electric Company, Schenectady, N. Y.): This paper was of considerable interest to a group of us in the General Electric Company, because over a year ago we undertook to study this same problem. From our work, application guides for the protection against lightning of metal-clad switchgear and unit substations were formulated and presented in a paper in March 1949.[1] It is of interest to compare the results obtained by these two independent investigations.

The following general conclusions can be drawn from each investigation, that where exposure is through a short length of cable and there is an adequately installed lightning arrester at the junction of the cable and overhead line:

1. Additional lightning arresters are required in the metal-clad gear if the application is in the 13.2-kv class.

2. No lightning arresters are required in the gear if the application is in the 4.16-kv class.

These similar results were obtained through somewhat different assumptions. In this paper, the decision on whether or not additional lightning arresters were required was based on whether the lightning-arrester characteristics with their plus tolerances together with lightning-arrester lead drop exceeded the demonstrable impulse strength of the switchgear. In our investigation, we also used plus tolerances on the lightning arresters, but these were somewhat larger than they would be today because of downward industry changes in these values. Our criterion was that these lightning-arrester characteristics must be 80 per cent or less of the demonstrable impulse strength of the switchgear. This 20 per cent margin was intended to cover such variables as lead lengths, multiple strokes, and the other factors that are present in every application and are not known with preciseness.

Because of these differences in assumptions, our solution of "how long is a short cable" is somewhat more conservative than the results given in this paper, but in general, the actual results have little practical differences in them. There is a minimum length cable that can be used in any given application, and this length is dictated by the height of the pole on which the cable user is located at the junction of the cable and overhead line, and the location of the pole with respect to the substation site. So regardless of whether 20 feet or 34 feet, to take a specific example, are specified each of these cable lengths are shorter than can be practically installed.

With regard to the type of lightning arresters to be used in metal-clad switchgear, this type of gear should have the best available. We feel definitely that the station-type lightning arrester should be used. We have developed a type of porcelain housing for this lightning arrester for

this application which can be mounted on close centers in these equipments where space is at a premium. Each feeder position in the metal-clad switchgear has room for a cable pothead and a set of lightning arresters so no additional compartment is necessary if station lightning arresters are specified.

In general, I would like to commend the authors on their work on the propagation of surges through cable. In general, there appears to be a dearth of information on this subject, and the work they have done will undoubtedly pave the way for further investigations.

REFERENCE

1. LIGHTNING PROTECTION OF METALCLAD SWITCHGEAR AND UNIT SUBSTATIONS CONNECTED TO OVERHEAD LINES. Committee on Application of Lightning Arresters to Switchgear. *General Electric Review* (Schenectady, N. Y.), March 1949.

F. E. Andrews and **W. H. Hatch** (Public Service Company of Northern Illinois, Chicago, Ill.): The authors have presented a useful analysis of a problem of considerable importance, and of which there has been some lack of understanding. This analysis appears to be confined to paper-insulated cable with complete metallic covering such as provided by a lead sheath.

It would be desirable to have similar information on types of cable coming into more general use on distribution systems having only partial metallic covering. With the advent of buried cable for rural service and the demand for underground distribution in certain classes of housing developments and subdivisions, the use of cable interspersed in overhead distribution systems is rapidly increasing. Aerial cable should also be considered, as it also may be connected to open overhead conductors and will involve a wide range of cable lengths.

These buried and aerial cables are commonly of oil-base rubber-compound insulation and will have partial metal coverings. In the buried cable this may take the form of a number of spiral strands with some spacing between them. In the aerial cable, it will consist of the messenger and the spiral metal binding tape which holds the rubber-insulated conductors to the messenger. In both cases, this metallic covering will generally be the neutral conductor. Associated with this cable will be overhead distribution transformers and fused cutouts of the 5-kv insulation class.

The possible effects of the partial metal covering and the different impulse characteristics of the rubber-compound insulation are added factors which make the analysis of the problem difficult for the distribution engineer. It is hoped that the authors, in their published closing discussion will include comments and some information, at least qualitative, on the above aspects of the cable protective problem.

E. L. Harder (Westinghouse Electric Corporation, East Pittsburgh, Pa.): I would like to comment on the use of the computer in this problem. It requires no very great imagination to realize the enormous potentialities opened to us as electrical engineers with the advent and perfection of large-scale computing machinery. However, as with most activities, those of us working closely with this equipment have these potentialities impressed on us more vividly than otherwise.

It is only five or six years since the first studies of the type just described were made on equipment which was the forerunner of the analogue computer. These studies were for open-wire line rather than cable but involved a distance between the lightning arresters and the transformers. The studies were made by H. S. Kirschbaum and myself as part of a joint study with the Philadelphia Electric Company directed toward improving the lightning protection in the 230-kv Plymouth Meeting station. A line section, lightning arrester, and transformer were represented on the computer to test out the method and check it against theoretical analysis, and then the complete station was represented to determine the degree of protection afforded by lightning arresters in various locations.

The computer equipment and techniques used in these studies were generally the same as had been devised and used earlier by Evans, Monteith, and Witzke[1] for study of recovery voltages and switching transients on power system. The only difference was the introduction of lightning waves, scaled down in time, in place of the 60-cycle voltages and the use of inductor coils of lower loss. These had been developed for studying mechanical systems. Nonlinear elements also were introduced for representing the lightning-arrester characteristic.

Since that time the lightning protection of a number of particular substations has been studied by this technique, for example, substations of the Potomac Edison system and of the Metropolitan Edison system.

This is a perfectly practical thing to do and quite useful if one wishes to obtain a clear picture of what goes on when surges enter a particular substation. It requires analysis, based on the line construction and exposure, as to what surges must be considered as entering the station, an analysis similar to that which Witzke and Bliss have so ably carried out in connection with the cable problem.

There is a definite need for two kinds of studies.

1. General studies of typical situations which are simple enough to generalize so that the results can be widely applied and can form the basis for industry standardization of practice. The study just outlined by Witzke and Bliss is in this category.
2. Specific studies of particular stations. Seldom are two stations exactly alike. The exposures differ. The arrangements and spacings differ. Each one requires consideration of some different aspect of the protection problem. We must not under-estimate the value to an individual company and to the industry of these specific studies of important or typical stations. In addition to providing a much more accurate picture of the individual case, they show up the importance of practical station design practices which can later be incorporated into the general studies. They reveal what general situations should be subjected to study by the industry as a whole. Computers are available for this work on a similar basis to a-c calculating boards.

In a paper entitled New Techniques on the Anacom[2] an analogue or representation for corona was described, so that it is now possible to represent accurately the effect of corona on the travelling waves entering stations and affecting the protection problem.

Both corona and transformer saturation are being represented in current studies of switching transients on high-voltage lines.

Other new types of studies taking place on large scale computers which I believe might be of interest in pointing out the potentialities of computers are:

Series capacitors—the complex action of currents and voltages when protective gaps are operating during line faults. How else would one study the relaying currents and voltage prior to the actual installations?

Carrier current—during the year studies were made of carrier propagation over a 5-terminal line. A smooth line representation over the entire carrier frequency spectrum were obtained by the use of 150 pi sections. The 50 to 150 kc was scaled down about 100 to 1.

Transient performance of potential devices for various burdens and faults can be analyzed.

Gas flow, fluid flow, and so forth all can be handled now in addition to electric current flow since general nonlinear elements are available.

The open phase and fault to ground or the simultaneous faults on twin circuit lines need no longer be a mystery as a general method of solution by computer is now available for this problem.

These potentialities of the analogue computer are quite unlimited and are something to stir the imagination indeed.

2. NEW TECHNIQUES ON THE ANACOM, E. L. Harder, J. T. Carleton. *AIEE Transactions*, volume 69, part I, 1950, pages 547–56.

E. Beck (Westinghouse Electric Corporation, East Pittsburgh, Pa.): Mr. Witzke and Mr. Bliss have based their recommendations on certain characteristics of the lightning arresters located at the junction of the cable and the overhead line. For distribution lightning arresters they have assumed the maximum industry figures with which we agree. For station and line-type lightning arresters they have used values that are the average industry figures plus one-half the industry tolerance published in a recent AIEE Committee report.[1] For station lightning arresters, for example, the industry tolerance in that report is 15 per cent, so Mr. Witzke and Mr. Bliss have used a value for the lightning-arrester discharge voltage which is $7^1/_2$ per cent higher than the industry average. Consequent to the publication of the AIEE report, the lightning protective devices section of the National Electrical Manufacturers Association announced new tolerances for the discharge voltages of station and line-type lightning arresters, namely 10 and 15 per cent instead of the former 15 and 20 per cent. For station lightning arresters then, the value used by Mr. Witzke and Mr. Bliss

is really three-fourths of the maximum industry tolerance. NEMA also has suggested a protective level for use as a basis in insulation co-ordination problems, found by adding to the average two-thirds of the maximum tolerance in the case of station arresters. This would be the average performance plus $6^2/_3$ per cent.

It is probably subject to further discussion and debate whether these suggestions are practical or whether the full industry tolerances should be used. If Mr. Witzke and Mr. Bliss had used the new tolerance of 10 per cent for station lightning arresters, the cable lengths would have been a little more conservative. It seems to me, and this is now opinion and not complete conviction, that Mr. Witzke's and Mr. Bliss' suggestions are conservative. They should be. However, it has not been brought to our attention that lightning damage to cable-connected equipment with lightning arresters installed only at the pothead, is prevalent; perhaps the result of the as yet imponderable probabilities mentioned by Mr. Witzke and Mr. Bliss. Since these are still undetermined it seems to me that information from the users of cable-connected equipment regarding their experience would be most helpful in providing some kind of a confidence factor, and I would recommend that such information be accumulated.

For example, from Table VI of the paper, it appears that line insulation can be a potent-factor and that on a highly insulated line, 1,000 kv for example, the installation of a protective device which would spark at 250 kv, located 125 feet from the pothead, would decrease the chances of lightning damage to the cable-connected equipment, since for strokes beyond the protective device on the line and for strokes on the other side in the vicinity of this protective device this line-type protective device will operate and the duty on the lightning arrester at the pothead and therefore the terminal equipment will be reduced. This is only one of the probability factors that may well operate in practice to give a conservative tinge to the recommendations. Considering these factors, the practical picture may actually not be altered much by using the present maximum industry tolerances or the NEMA suggestion for station and line-type lightning arresters instead of the compromise adopted by Mr. Witzke and Mr. Bliss. However, the use of the maximum tolerance with some allowance for the probabilities would be another method. The question affectively boils down to this, the user of cable-connected equipment must weigh the risks and his experience and the consequence of possible lightning damage in the equipment. The data on past experience would be of much value in this connection.

1. PERFORMANCE CHARACTERISTICS OF LIGHTNING PROTECTIVE DEVICES, AIEE Committee Report. *AIEE Transactions*, volume 68, part II, 1949, pages 1330–33.

R. L. Witzke and T. J. Bliss: The discussion by Mr. Andrews and Mr. Hatch, as well as the one by Mr. Opsahl, points out the need for surge-protection application data for installations involving cables without a metallic sheath, or with a partial metallic covering. The authors agree that this information is desirable, and additional studies should be made in the near future. With no metallic sheath, the cable surge impedance and the velocity of surge propagation are more difficult to determine, because these constants depend upon the location of the conductors relative to ground, or metal ducts. Careful consideration also must be given to the resistance of the lightning arrester ground.

Mr. Beck's comments relative to the installation of additional lightning arresters on the line, at some distance from the cable pothead, is pertinent. Surges originating beyond this point will be limited in magnitude by this second set of lightning arresters, and the duty on the junction-pothead lightning arresters will be reduced considerably. In many applications the installation of additional lightning arresters one or two spans from the cable junction may be preferable to the installation of lightning arresters at the equipment end of the cable. This is particularly true in those cases where the installation of lightning arresters at the equipment is difficult because of space limitations.

Mr. Hunter recommends the use of station-type lightning arresters in switchgear assemblies on the basis that the best available lightning arrester should be used. The data presented by Mr. Wortman show that the duty on the lightning arresters in the switchgear is moderate, because the junction-pothead lightning arresters discharge a large part of the total current. For this reason distribution lightning arresters should be generally satisfactory for this service.

Mr. Abetti has asked whether or not transformer losses have any important influence on the surge voltages at the transformer terminals. Our investigations indicate that these losses should have less influence than the cable losses, which we concluded were of secondary importance for cable lengths up to 1,000 feet. Investigations made by Mr. Teague and Mr. Rademacher showed no appreciable difference in results between tests made with actual and simulated transformers.

The Metrotype System of Digital Recording and Telemetering

G. E. FOSTER
ASSOCIATE AIEE

Synopsis: A measuring system has been developed which will automatically measure and record in numerals at predetermined intervals items which can be measured electrically. The readings may be telemetered over a single channel for any distance. The paper describes briefly, with the aid of block diagrams, the process by which the instrument measures, telemeters, and prints the readings on a "log sheet."

THE years since the war have been highlighted by ever increasing costs of production. With such a condition existing, the need for automatic devices to monitor and/or control processes becomes increasingly urgent. The need for devices to provide data is felt even more pressingly. If additional labor to read curves, instruments, and so forth, can be eliminated and the data obtained in numerical form, even further advantages can be obtained.

The Metrotype is a system of making measurements and recording them in digital form. If telemetering is required, each reading is transmitted singly and recorded in tabulated form. Only one transmission channel is required and this can be of telegraph quality. The name Metrotype is derived from the Greek words metron, to measure, and typo, to mark.

There are several ways in which an electrical quantity may be measured. The usual ways are an indicating instrument or a curve-drawing instrument. The method of making a measurement by the direct writing of the numbers has not been generally used other than in digital counting machines (the cash register or adding machine). Before the war, several machines which printed electrical measurements were built and used,[1] but they were subject to many difficulties. A machine such as the Metrotype which can make sequential readings and transmit these readings to a distant point is an improvement on the prewar machines.

The machine to be described will select in sequence the quantities to be measured, make the measurement, transmit these readings as far as desired, and record them in numerical form properly tabulated. A complete 3-digit reading can be measured and recorded in 0.8 second. It combines the electronic computer technique with that of the printing telegraph. The result is a measuring instrument which makes readings automatically in numerical form. Standard paper with as many copies as desired may be used.

System Arrangement

The block diagram of Figure 1 indicates the interrelationship of the various components. The master control is inherent in the teletype (*TTY*) transmitter. This unit controls a line relay which in turn will operate a standard teletype printer. It is started by a clock, manual switches, or any other starting circuit, and generates the teletype codes[2] as required by the master switch and the number mixing relays.

In order to sequence the operations properly, a master switch is provided. Stepping of the master switch is controlled by the *TTY* transmitter. The master switch establishes the proper framing functions for the printer. It determines when the circuit selector will operate. It provides a method for homing the circuit selector to the proper starting point, and it controls the operation of the print sequence control. At the end of the printing cycle it turns off the printer and equipment.

The print sequence control is initiated by the master switch after the printer has been properly framed. As it runs, it selects the circuit to be measured, clears the electronic counters, pulses the step voltmeter, operates the digital sequence of the number mixer, and inserts the space function following the numbers.

The quantity to be read enters through the circuit selector and appears as a voltage at the step voltmeter. The latter generates a number of pulses proportional to the voltage being measured. The pulses are counted by the electronic counters and held in the form of an electrical condition in the various stages of the counter.

The number mixer consists of relays and

Paper 50-84, recommended by the AIEE Instruments and Measurements Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted November 2, 1949; made available for printing December 8, 1949.

G. E. Foster is Chief Engineer with the Metrotype Corporation, Chicago, Ill.

Figure 2 (left). Time relations

Figure 3 (right). Teletype transmitter

tubes which receive control information from the electrical conditions of the electronic counters and the print sequence control and translates this information into teletype code. The teletype code appears on the contacts on the number mixer relay where it is read by the teletype transmitter and transmitted to the printer. The space function also is inserted at the proper time by means of relay a controlled by the print sequence control.

Timing Sequence

The timing of some of the more important events in the printing sequence is shown in Figure 2. The upper row *a* shows the teletype codes transmitted during the starting interval, the printing interval, and the stopping interval. The selection of events is controlled by either the master switch or the circuit selector switch. The controlling element is shown as curves *b* and *c* of Figure 2. Following the sequence of events, the start of the master switch puts out a blank interval to start the printer, and then cuts in the circuit selector and waits until the circuit selector has reached home position. During this interval no codes are transmitted. When the circuit selector reaches home position, control reverts to the master switch which then transmits carriage return and figures functions to insure that the printer is in a starting position at the left side of the page and in condition to print numbers. Control again returns to the circuit selector switch and remains there for the remainder of the printing interval. At the end of the printing interval control reverts to the master switch which, in turn, transmits the carriage return, line feed, and stop function codes. The machine then turns off at both the measuring and printing ends.

Curve *d* of Figure 2 shows that the print sequence control is energized only during the printing interval. This prevents any of the print sequence functions from interfering with the framing functions as determined by the master switch. The pulses which step the print sequence control are shown as curve *e* of Figure 2. Curve *f* shows that a pulse to the step voltmeter occurs at the beginning of the blank interval of each printing cycle. This blank interval provides a time interval for the step voltmeter to make the measurement. It is 0.16 second in duration. As indicated by curve *g*, a clearing pulse is transmitted to the various counters at the beginning of the space interval to remove the previous count from the counters before a new count is received. Curve *h* of Figure 2 shows when the circuit selector steps. During the homing interval it steps rapidly until it reaches home. During the remainder of the printing cycle it steps at the beginning of the space function.

Teletype Transmitter

Figure 3 is a block diagram containing the essential information on the operation of the teletype transmitter. The principal component is a tube arrangement which acts like a ring counter of eight tubes operated one at a time under the control of an oscillator. The first two tubes of the ring counter generate a marking interval for the teletype printer and the next tube generates a spacing interval. These are similar to the standard marking and spacing intervals used for synchronizing the printers. The remaining five counting tubes are used for generating the coding pulses for the teletype printer. The code pulses pass through contacts of the number mixing relays or the master switch, which allow the proper codes to pass to print the information or function desired at that point in the operation sequence. The coded pulses are mixed with the stop and start codes generated by the first three tubes of the ring counter and passed to an amplifier which in turn controls the transmitting relay. On the contacts of this relay appear normal teletype pulses used for control of the telephone line circuit connecting to the printer. Although a mechanical transmitter could be used in place of the electronic transmitter outlined, the need for auxiliary control pulses to operate other electronic equipment makes an electronic pulse generator more desirable than a mechanical one. This is due to the difficulty of obtaining mechanical contacts with no chatter or bounce. An electronic pulse is derived from the tube which generates the fifth code impulse to operate a relay which in turn steps the master switch, and in addition provides a pulse to the step print sequence control.

Print Sequence Control

The print sequence control operates in a manner analogous to that of the transmitter. However, it contains only five counters in the ring instead of eight. It is triggered by the pulses received from the transmitter. These pass through a control circuit (operated by the master switch) before reaching the print sequence tubes in order that operation can occur only during the printing interval. Figure 4 shows a block diagram of the essential features. As the ring counter steps,

Figure 4. Print sequence

Figure 5. Step voltmeter

various auxiliary conditions are controlled. The blank interval is provided to permit time for the measurement. If three digits are to be printed the tubes of the 100's mixer are energized. The next step energizes the 10's mixer, the fourth step energizes the 1's mixer and also the auxiliary relay which energizes the coil of the circuit selector stepping relay. In the fifth step the circuit selecting relay moves to the next position. At the instant the print sequence is transferred to the first step a pulse is transmitted to the step voltmeter giving the command to make a measurement.

The Step Voltmeter

The actual measurement is performed during the blank interval of the print sequence by the step voltmeter, shown in the block diagram of Figure 5. On receipt of the count command pulse from the print sequence control, a pulse is generated by the pulse shaper which in turn causes the time delay tube[2] to function. The time delay tube does two things. It starts a phantastron,[3] and it also operates the oscillator control tube to hold the oscillator in an off position. At the end of the delay interval the oscillator control tube turns on the oscillator. Meanwhile, the phantastron has been started and it runs for a time interval determined by the d-c signal voltage applied to its plate. It operates through an amplifier to turn the oscillator control tube off. As the oscillator runs, a number of pulses will be generated proportional to the voltage being measured. The zero set is a voltage introduced into the phantastron to permit its running time with no signal to exactly equal the time delay interval, and thus, with no signal, the oscillator never starts.

Counting and Number Mixer

The pulses obtained from the oscillator are counted by four tube binary counters arranged in decades.[4] As many decades are provided as are required by the digits needed. Figure 6 indicates the general arrangement. The number mixer permits the selection of the proper digit as commanded by the print sequence control and, in addition, as determined by the count existing in the selected decade of the counters.

Voltages from the number mixer operate through the number mixer amplifier to operate the number mixer relays. It can be seen readily that with four relays ten possible contact arrangements can be provided. These contacts therefore set up the teletype codes required for each digit from one to zero. Table I shows the relays operated for each number from zero to nine.

Arrangement of Components

A complete machine is shown in Figure 7. This machine in addition to performing the functions outlined previously also will accumulate totals, shift ranges, and print on two machines. Two machines were required since the user desired more columns than were available on one machine. This can be carried as far as desired. In the rack from top to bottom are located a control panel, the tube circuits, the transmitting relays, the circuit selecting relays, and the power supply. Although the teletype machines are shown alongside the rack, they may be located at any distance provided a satisfactory communications link is used for interconnection.

A section of one of the log sheets obtained from one of the machines during a test period is shown in Table II. The machine was designed to read current in the outgoing lines of a distribution center and to accumulate totals for zone loads. The vertical columns are the readings in tens of amperes for a given line or total and the horizontal readings were made automatically once each half-hour. In this particular case the form for a log

sheet is preprinted. Approximately 20 vertical columns can be printed on a page. Such features as automatic page advance at the end of the day can be readily obtained. These readings were made at the control center of the supervised distribution substation.

Fields of Usefulness

The usefulness of this instrument is most apparent on any continuous flow processes, such as electric power generation and transmission, gas transmission, oil storage or transmission, steel making, paper making, oil refining, chemical processes, and so forth. A portable type can be used in testing new installations. The readings of many different quantities related to the process such as time, temperature, pressure, flow, voltage, current, counting, integrated flows, and so forth, may all be assembled in a related manner on a single instrument and on a single log sheet. The record may be made at the most essential point whether feet or miles intervene. It is particularly useful in those operations which are fully automatic or where the man power available is low, or desired to be lowered.

The use of this instrument permitting the elimination of the human element results in a more accurate and legible record. All readings are taken as scheduled either by clock contacts or by some element of the process whether or not the operator is busy on other duties.

Where records are used in more than one office for various purposes the instrument will produce up to 20 good carbon copies. Copies containing vast amounts of data are readily mailed or stored. If more than 20 copies are required, a ditto carbon or ribbon may be used and up to several hundred copies may be obtained.

Figure 7. Rack and two printers producing 40 columns with totals and subtotals

In addition, if readings must be obtained at two or more locations, as many additional printers as desired may be used.

The Metrotype system for digital recording and telemetering is a measuring system which produces records in the form of columns for separate quantities, lined up automatically for time or some other factor. Transmission may be made any distance and may include totals or any other computation as required. The following are incidental benefits from the use of the Metrotype: greater accuracy, greater legibility, duplicate records, uniform timing of readings, and each reading distinct from all others.

Discussion

N. G. Larson (Commonwealth Edison Company, Chicago, Ill.): This discussion is restricted to describing an application of the device in the power field. In Chicago, the Commonwealth Edison Company is using a number of these machines, principally to record ampere load readings of 12,000-volt lines originating in various generating stations or 66,000-volt substations. The 4,000-volt radial distribution system throughout the city is supplied from step-down 12,000/4,000-volt distribution substations. These substations are geographically grouped together by 12,000-volt tie lines and the group supplied by radial 12,000-volt lines originating at one supply center. This center is the 12-kv switchhouse at either a generating station or 66,000-volt substation. The number of 12,000-volt supply lines per group varies from three to eight.

In stations where manual recording is used, the sequence of line readings on the data sheet is determined by the location of the line ammeters on the instrument panel. Consider, for example, an 8-line substation group. In this case the lines are supplied from eight different line busses at the 12-kv switchhouse. The readings are necessarily scattered throughout the data sheet, resulting in a considerable time interval between the first and last reading, particularly in large stations having as many as 50 outgoing lines. The determination of the group maximum from the data sheet at any particular hour requires the use of a special template, and the determination of the daily maximum requires considerable cut-and-try computation.

In stations where machine recording is used, all lines to the same substation group are grouped together on the automatic meter. This results in: more reliable coincident group maximum because of a very large reduction in time interval required to record all of the line readings; simplification in comparing individual line readings; elimination of need for cut-and-try computation in determining group maximums since the group line readings are automatically totalized; insurance that readings are taken on scheduled time; and the ability to take special readings at any time by merely pushing a button.

The machine has been found to be particularly useful in the case of large unattended supervisory controlled 66,000-volt substations. Substation groups are supplied from these stations by 12,000-volt radial lines in the same manner as from generating stations. The line-ampere readings are teletyped to the remote supervisory center, and are there recorded. The operators at the control center can obtain special readings at any desired time.

Our load dispatchers make frequent use of these special readings. For example, such readings are taken at supervisory control center and relayed by telephone to load dispatcher whenever it is required to take a line out of service, or during times of unscheduled line outage. With system data readily available, proper action can be taken immediately by the dispatchers. If these data were not available, it would be necessary to dispatch a travelling operator to the unattended substation and wait for his report, and usually to perform insurance operating in the interim.

New Techniques on the Anacom—Electric Analog Computer

E. L. HARDER
FELLOW AIEE

J. T. CARLETON
ASSOCIATE AIEE

Synopsis: The paper outlines the direct-analog approach used on the Anacom and describes the sigma amplifier which combines adding, integrating, delay, and other operations into a single computer amplifier and results in an improved computing technique. Examples include a speed-regulating system, and systems of simultaneous differential equations such as the aerodynamic equations of flight of an airplane. An adjustable nonlinear resistor and other functional devices are described, together with their use in analogs of fluid flow, saturating iron cores, magnetic amplifiers, and hysteresis. An analog for corona is given.

THE Anacom[1] was designed as a general purpose electric analog computer based on several years' experience with smaller scale and special purpose computers. These were the electric transients analyzer,[2] the servo analyzer,[3] the mechanical transients analyzer,[4] and the pilot model of the general purpose computer.[5] These transient computers, or solvers of ordinary and partial differential equations had in turn been built up from a background of experience with the d-c and a-c network calculators,[6] machines primarily for solving the short-circuit, steady-state, and stability problems of electric power systems.

The general purpose electric analog computer, the Anacom, was started in 1946 and completed in 1948. However, because of its compartmented character, problems were started before its final completion. In the approximately $1^1/_2$ years of its operation some 43 different types of problems have been solved, involving a total of 141 distinct problems.

Most of these problems have had to do with the design, application, or operation of electric and mechanical machinery and equipment or with studies of switching transients and lightning phenomena in electric power systems. These are all physical problems that are reducible to mathematics. However, several purely mathematical problems have been solved, which, though they may have physical interpretations, did not arise directly therefrom.

In the course of this work the analog techniques have been vastly improved resulting in a more systematic approach of great power and flexibility. It is the purpose of this paper to outline some of these techniques and to indicate their use in typical problems.

The Direct-Analog Method

The Anacom is a general purpose computer composed of a multiplicity of integral computing elements and thus can be used to solve problems by a variety of techniques. However, it is particularly powerful in the direct-analog approach[7] which now will be described.

Figure 1 (B) illustrates the same problem analyzed by the conventional analog approach, and also by the direct-analog method, Figure 1(C). In the direct-analog method all elements of the physical system, or nearly all, have their counterparts in the analog and as such are under the direct and independent control of the operator. To study the effect of varying a certain element of the system the operator need only vary the corresponding element of the analog. In rare cases this may involve a lessened mathematical generality and the use of a few

more elements. Some of the advantages of a direct 1-to-1 correspondence between analog elements and system elements in design work are quite apparent. However, not until one enters the nonlinear domain of saturation, of fluid flow, of discontinuous functions, of hysteresis, and limiting action does the great advantage of the direct-analog method become truly evident. Rapid and accurate solutions of complex nonlinear problems can be obtained readily.

The more conventional method, illustrated in Figure 1(B), which of course also can be used on the Anacom, involves reduction of the mathematical equations to simplest form and combining terms wherever possible. This step is desirable even if the direct-analog method is used, since it shows the actual combination of parameters on which the solution depends. The highest order derivative is usually integrated by successive integrators until all the required derivatives have been obtained. These then are operated upon by addition, multiplication, and other functional processes as indicated by the equation so that the highest order derivative, which had been assumed at the start to be available, is thus generated, as shown in the figure. The computer as thus connected is a direct analog of the equation but is an indirect analog of the system.

This method has the distinct advantage of a systematic mathematical approach and has been most successful in many years of operation of the differential analyzer.[8–10] Also, in many scientific and mathematical problems the direct analog does not have the same advantages that it has in design work. For example, in solving the complex equations of cosmic-ray paths the direct-analog method is certainly not indicated.

One would be foolhardy to attempt to delineate the precise field of applications of these two methods, as they depend a great deal on the computer characteristics, the nature of information sought, whether a general or specific problem is studied, the relative costs of preparation and interpretation as compared with actual computer costs and many other factors. However, with a high-speed computer, and engineering problems of design and application, the direct analog, wherever it can be devised readily, offers considerable advantage. In design particularly, the designer may have only two or three of a total of fourteen or fifteen system parameters at his disposal to vary. The direct analog enables these to be varied with a minimum of effort, preparatory computation, and subsequent interpretation. It makes possible the direct determination of optimum solutions obtainable with the variables under the designer's control. This will become more evident in the example to follow. Practically all of the problems on the Anacom to date have been solved by the direct-analog method.

The Sigma Amplifier

The use of the feedback amplifier as a computer or simulator element is well known and will not be discussed here except to show the particular type, and the use made of it, in the Anacom. The general functional relationship obtainable between output and input voltages is indicated in the top row of Figure 2. The resulting relationships for various input and feedback impedances are given in the subsequent rows, together with the

symbolic representation used in computer schematic analogs. Note that the operator $p = d/dt$ is utilized to symbolize differentiation, $1/p$ integration, $(1+p)$ advance through a time constant, $1/1+p$ delay of a time constant, and so forth.

The particular amplifier used for this purpose can be supplied with either push or pull input signals and supplies both push and pull outputs. It thus obviates the need for separate sign-reversing amplifiers. This differential input arrangement also makes possible operation of the amplifier grounded although neither side of the input voltage is grounded. Because of its multiplicity of uses, one of which is as an adding amplifier, and for want of a better name, this device has come to be known as a Sigma amplifier.

Through its use, ungrounded operation of amplifiers, multipliers, and other electronic gear, as well as the use of transformers in the analogs, has been largely eliminated. Voltages are developed to ground and added in adding amplifiers instead of in series loops as was common in earlier analogs. This greatly simplifies the electronic equipment making possible common power supplies, simplifies shielding, and results in a more systematic procedure for determining the analog.

Speed Regulator Analog

The four steps usually present in the over-all solution of a problem by electric analog may be illustrated by the four parts of Figure 3. The problem here is the determination of speed versus time for impact loads and for sudden changes of the speed setting. Solutions are required for a large number of values of the parameters, and so the analog method is to be used.

The system shown consists of a d-c motor with fixed field supplied by a generator whose field is controlled by a Rototrol through an intermediate exciter. The Rototrol responds to deviations of the speed (tachometer voltage) from the reference voltage setting. Speed droop with motor load is provided by feeding back the commutating and compensating field drop into a separate Rototrol field. Stabilization is afforded by degenerative feedback from the exciter and by damping transformers which feed back derivative functions of exciter and generator voltage. Base excitation is supplied through still another Rototrol field to reduce the unregulated speed error and hence increase the accuracy of regulation for a given regulator gain.

It is a matter of machine and regulator theory requiring a specialist in this field to reduce this system to its equivalent, Figure 3(B), and its corresponding equations. It is an important matter, sometimes overlooked, that between the actual physical problem and its mathematical expression, with such approximations as are permissible in the particular art, lies a whole field of knowledge with which the operator of a general purpose computer will not in general be familiar. The mathematical expression of the problem is strictly a function of the specialist in the field of the problem, working of course in conjunction with the computer staff to express the problem in proper form and with sufficient information. Practically, there is considerable overlap in these two functions since analog computers have usually started as special purpose computers for particular problems, and the computer engineer is, or soon becomes, skilled in the art in question.

Figure 3(C) gives the schematic analog which obeys the same differential equations as the system in question. It is made up by reference to tables of basic

Figure 7 (right). Sigma amplifier analog for representing the aerodynamic equations of flight of a high-speed airplane

Figure 8. Nonlinear resistor

(B). Resistance increasing with voltage
(C). Generalized nonlinear resistance
(D). Basic limiters, current, and voltage

analogs that correspond to specific functional relationships. Figure 2 is an example, giving some of the functional relationships obtainable using the Sigma amplifiers. Other tables are available for circuit elements connected in various ways, for nonlinear elements, and for other functional devices. Other analogs are devised as needed, usually from combinations of existing computer elements. Limitations are more likely to occur in lack of essential knowledge of the problem than in the inability to analog it.

The next step is distinctly a computer job of developing the schematic analog into a connection diagram, such as Figure 3(D), taking proper account of scale factors, computer time base, impedance levels and the like. Figure 3(D) is the actual analog setup for this problem. It is a direct analog having 1-to-1 correspondence between fourteen parameters which completely describe the system and the same fourteen parameters in the analog.

Impact load is simulated by unit function of current in the capacitor, giving an initial rate of decrease of its voltage, which is analogous to speed. Sudden change of speed setting could be represented by inserting unit-function voltage in the speed loop. However, it is just as accurately and more conveniently added to the speed signal in the first sigma amplifier. Typical solutions for these two conditions are shown in Figure 4.

The second sigma amplifier is simply an unloader or isolator. Usually one resistance-capacitance circuit can be loaded on another without material interaction by using low and high impedance bases for the two, while retaining the correct time constants. Use is made of this method in the analog of Figure 3.

Hysteresis Analog

As electric machines usually have hysteresis to some degree, the flux and hence the generated voltage is not a single-valued function of field current but depends on past history of the iron also. Since this functional relationship can be only very approximately expressed and since the effect is relatively small, a rather approximate analog is adequate to study the effects. The analog may be that shown in Figure 5(A), or alternatively a bridge of diodes with a single battery may be used. For rising field voltage, e_1, the voltage e_2, which corresponds to machine flux or armature voltage, is below the voltage e by a fixed amount equal to the battery voltage. On falling voltages e_2 is above the voltage e, which is analogous

Figure 9. Nonlinear resistor panel containing two 20-line-segment units

to field current, by the battery voltage. Thus whenever the time derivative of field current changes sign, a finite change in field current, voltage e, is required before the proportional current-flux relationship is resumed. This action is closely equivalent to actual hysteresis in machines. If the ratio of width to height of the resulting parallelogram-shaped hysteresis loop is made the same as for actual loops, a reasonably accurate solution for the effect in a regulating system can be obtained on the computer.

The solutions for three values of hysteresis are shown in Figure 5(B). The upper three oscillograms show the flux-current locus traced during the oscillation following a sudden change of speed setting. The lower loops of these oscillograms correspond to the oscillation during return of the speed setting to normal, the complete operation being repetitive on the Anacom.

In the lower three oscillograms which are the speed-time plots, the effects of hysteresis can be noted. A moderate amount of hysteresis in the exciter has little effect, whereas a greater amount considerably increases the overshoot and recovery time. Note the presence of two distinct limiting solutions depending on the initial condition of the flux, voltage e_3, which can differ from zero by plus or minus the battery voltage, even though e_1 is initially zero.

Simultaneous Equations

Figure 6(A) illustrates an analog previously described[11] representing simultaneous equations. The general method of attack is to devise a multimesh circuit in which the self and mutual impedances represent the coefficients of the respective terms.

Passive systems characterized by limited bilateral mutual terms may be represented with ease for equations of three or less variables. Special cases involving greater numbers of variables are often easily represented. The scope of this analog may be broadened somewhat by the use of transformers provided that spurious effects due to the inability of the transformer to perform ideally fall outside the frequency spectrum being investigated.

Active systems, characterized by unilateral impedances, require the use of amplifiers. Referring to Figure 6(A), it may be seen that amplifiers may be required to operate ungrounded, requiring specially shielded power supplies and introducing appreciable stray capacitance. The use of isolating transformers in active systems is seriously limited. The spurious results over the frequency range from zero to infinity must not produce instability. Should the effect of the transformers be appreciable, low-frequency motorboating or high-frequency oscillations will alter the solution.

The application of sigma amplifiers facilitates the analoging of simultaneous equations. As an example, consider the lateral equations of flight of a hypothetical high-speed airplane.

Roll equation ϕ = Angle of roll

$$\left(1+p\frac{I_x}{-C_{l\frac{d\phi}{dt}}}\right)\phi=-\left(\frac{C_{\frac{d\psi}{dt}}}{C_{l\frac{d\phi}{dt}}}\psi+\frac{C_{l\beta}}{pC_{l\frac{d\phi}{dt}}}\beta+\frac{C_{l\delta}}{pC_{l\frac{d\phi}{dt}}}\delta\right)$$

Yaw equation ψ = Angle of yaw

$$\left(1+p\frac{I_z}{-C_{n\frac{d\psi}{dt}}}\right)\psi=-\left(\frac{C_{n\phi}}{C_{n\frac{d\psi}{dt}}}\phi+\frac{C_{n\beta}}{pC_{n\frac{d\psi}{dt}}}\beta\right)$$

Side-slip equation β = Angle of side slip

$$\left(1+p\frac{2b\mu}{VC_{Y\beta}}\right)\beta=-\left[\frac{C_{L\phi}}{C_{Y\beta}}-\left(\frac{2b\mu}{VC_{Y\beta}}-\frac{C_L\tan\nu}{C_{Y\beta}}\right)\psi\right]$$

Servo equation δ = Deflection of aileron

$$(1+pT_4)(1+pT_5)\delta=-(K_\phi\phi+K_\psi 4)$$

All symbols represent constants except the dependent variables ϕ, ψ, β, and δ, and p which represents d/dt.

(A). Switched inductance analog
(B). Sample core analog
(C). Integrator and nonlinear resistor analog

Figure 12. Analog of magnetic amplifier with or without self-saturation

The analog of this system is shown schematically in Figure 7. All amplifiers are grounded and no transformers are required. Parameters may be individually adjusted. Note that the analog logically follows from the foregoing equations. The left-hand side of the equation is the output circuit of the amplifier and the terms on the right-hand side are the amplifier inputs. If required, a more detailed servo analog may be substituted involving velocity and position limits and backlash.

Figure 11. T-equivalent circuit of transformer and analog

Adjustable Nonlinear Resistor

The adjustable nonlinear resistor is the basis for a considerable part of the nonlinear problem solution on the Anacom. Consequently some consideration will be given first to the device itself. The circuit is a connection of rectifying elements, direct voltage sources, and linear resistors, connected as shown in Figure 8. With it monotonic (continually increasing) functions can be closely approximated by a series of straight line segments.

Resistance decreasing with current is obtained as shown in Figure 8(A). If switch S is open, positive portions of the current wave I flow through the upper resistors and negative portions through the lower resistors. For positive currents the effective conductance is G_0 as long as the voltage is 0 to E_1. In this region no current flows in G_1, G_2, G_3 since E_1, E_2, and E_3 act to the left, but current in this direction is prevented by the diodes. Above E_1 but below E_2 current divides between G_0 and G_1 and the effective conductance is $G_0 + G_1$. Similarly the curve shows the conductance effective in each region of positive and negative voltages.

This device permits simulating resistances which are unsymmetrical with respect to the current and voltage axes. The voltages E_1, E_2, E_3, E_1', E_2', E_3' and the slopes can be adjusted independently. The only limitation is that the slopes (current per-unit voltage) must be constant or increasing with increasing plus or minus voltage.

By reversing the rectifying elements the curvatures can be reversed and resistance increasing with current represented as shown in Figure 8(B). Again the positive part of the current wave I flows through the upper branches. E_4 is adjusted for zero voltage across the four branches at

Figure 13. Photoelectric arbitrary function device

Figure 14. Corona analog

(B). Wave shapes of line-charging current with corona, taken on the Anacom. The critical disruptive voltage equals 132 per cent of the peak of the normal line to neutral voltage

zero current, I. Then as the current I increases G_1 cuts out at E_1, G_2 at E_2, and G_3 at E_3. The conductance effective in each region is shown on the associated curve.

For convenience potentiometers are used in place of the multiple batteries. Diodes are arranged for reversal so that functions having reversals of curvature can be represented as shown in Figure 8(C). Again the conductances effective in each region are indicated on the associated characteristic curve. As the voltage E is raised certain conductances cut in and others cut out, producing any desired variation of conductivity G with E or I.

An example of the use of the nonlinear resistor is the analog of a deisel engine lubricating system. The characteristic to be represented for many of the passages is linear in the laminar flow region and approaches square law in the turbulent flow region.

Another example is in the representation of lightning arrester characteristics in power system studies of lightning and switching surges. The solutions give both the current in the arrester, needed for design purposes, and the effect on the system.

The adjustable nonlinear resistor is of particular value in fluid flow problems, for example, gas flow. A square-law characteristic (voltage proportional to square of current) can be represented to an accuracy of ±1 per cent (current correct within ±1 per cent of maximum current) by the use of five straight line segments covering any desired range. An accuracy of ±2 per cent can be secured with three elements, and ±5 per cent with two elements. Actual results are somewhat better than these theoretical figures which are based on sharp intersection of the straight lines. Other uses will be illustrated later in the paper.

The nonlinear resistor degenerates in the simplest cases to current- and voltage-limiter circuits, typical arrangements of which are illustrated in Figure 8(D). These are useful for representing backlash, hysteresis, limiting action, and other types of discontinuities.

In general this device provides an arbitrary function of either dependent or independent variables with the sole restriction that the function be monotonic, that is, voltage continually increasing with current or constant.

Figure 9 shows two panel-mounted adjustable nonlinear resistances, each equipped for ten straight-line segments in the positive current region and ten in the negative current region. The positive and negative current characteristics are entirely independent and of course the characteristic need not necessarily pass through the origin. The units shown in Figure 9 utilize electronic diodes. Other nonlinear-resistor units of the Anacom use crystal diodes. The range of back to forward resistance is of the order of 10^5 for the electronic diodes and 10^3 for crystal diodes, giving the former a greater theoretical range of maximum to minimum resistance represented. However, not all of this increased range is usable and the lower forward resistance of crystal diodes is advantageous in some analogs.

Analog of a Saturating Iron-Cored-Inductance Magnetic Amplifier[13]

Three basic analogs which have been used to represent the functional relationships involved in a saturating or saturable iron-cored inductance are shown in Figure 10. In two of these, (A) and (C), the normal magnetization curve is represented, whereas in the third, (B), hysteresis is represented, but a small sample of the actual iron is required.

The switched inductance analog is the simplest but least automatic and follows principles well known in analytic work with saturation.[13,14] It has been used to good advantage in studying the limiting action of transformer saturation on transient overvoltages in power systems. The point of switching is adjusted by the operator to correspond with points at which the flux passes the established threshold values.

The reason for the sample core analog may not be immediately apparent. In the computer representation of a power system the most suitable time-scale transformation is frequently 1-to-1, this bringing the frequencies involved into the proper computer range. However, the time constant of a transformer varies as

Figure 15. Corona representation in transient voltage studies

(A). Schematic single-line diagram of transmission line, one end open
(B). Oscillograms of voltage on phase A during line de-energizing operation

the square of its linear dimensions. Thus a 2-inch model of a 200-inch-high transformer would have a time constant 10^4 too low, or the winding resistance is 10^4 too high. The circuit of Figure 10(B) eliminates this resistance from consideration.

The integrator-nonlinear-resistor analog of Figure 10(C) combines flexibility with automatic operation and has been used in magnetic amplifier studies described recently.[13] As would be expected, it has been found quite adequate for study of saturation phenomena when representation of the normal magnetization curve is sufficient and not adequate if the phenomenon is dependent, to an important extent, on hysteresis.

The analog of a core with two windings is shown in Figure 11 and follows the conventional T representation of a 2-winding transformer. The magnetizing branch has been separated into linear and nonlinear inductances corresponding to mutual flux inside and outside of the iron core, to provide direct correlation with iron characteristics and coil form.

The use of this basic analog in the complete analog of a parallel-connected magnetic amplifier with or without self-saturation is shown in Figure 12. This representation proved adequate for representation of amplifiers without self-saturation but not for those with self-saturation. In the latter case the performance depends to a major extent on the relationship between the back current of the rectifiers and the current corresponding to the width of the hysteresis loop. It is important to note in this case that the computer accurately solved the equations given it. The difficulty lay in mathematically expressing the system. Comparison with tests quickly brought out this deficiency, resulted in an increase in knowledge, and improved techniques. The use of a computer requires accurate mathematical representation of the problem. Frequently the problem has not been approached mathematically before the computer became available. Thus the techniques must be developed cooperatively, initial solutions being checked with experience and tests to assure proper representation in later studies.

In machine studies the generated voltage produced by rotation is proportional to flux instead of to its time derivative. The analog for saturation is then more simple and is indicated in the lower row of Figure 2. Use of a nonlinear resistor, as described here, in the feedback position fulfills the equations in this case. It may be noted simply that both the ratio of armature to field voltage and the time constant are reduced by saturation at the higher voltages, as occurs in machines and as represented by the equations given, the function being the flux-current relationship.

Photoformer

The oscillographic arbitrary-function device,[14,16,17] which has been called a Photoformer, is a new technique of considerable promise in the analog computer field. It consists of the elements shown in Figure 13. As the beam is moved horizontally in accordance with one variable, a phototube and servo circuit makes it ride the edge of a template whose height at any point is proportional to the desired function. The vertical deflection voltage which is proportional to this height is the output or desired function.

A chief advantage of this device is that it is not limited to monotonic functions as is the adjustable nonlinear resistor device, but can generate trigonometric functions, for example, over a wide angular variation of several complete cycles. Useful and recurring functions can be stored and set into the computer merely by slipping a template in place and making a few adjustments.

The device is, of course, limited to functions for which a template can be cut and oriented with sufficient precision. For example, in representing the saturation characteristic of iron, a ratio of maximum to minimum slope of 10^3 or higher may be required. The nonlinear resistance can be set accurately for such ratios but the Photoformer template would be extremely sensitive to orientation with such steep slopes. Also where large numbers of nonlinear elements are required, the simplicity and economy of the resistor type dictates its use. There thus appears to be a definite need for both devices in the general purpose computer.

Corona Analog

A most interesting analog is that for corona on high-voltage transmission lines shown in Figure 14, which has been valuable in studying the action of corona in limiting transient overvoltages. Space does not permit the detailed theory to be given, but its principle of operation is as follows. As the voltage of a wire rises, no corona current flows until a critical disruptive voltage is exceeded. From this point until crest voltage a current flows, producing a space charge about the conductor. After crest there is no further current until the conductor potential falls to twice critical voltage below the crest voltage, when corona current flows until the next crest.

In the analog the batteries are set for the critical disruptive voltage. Until the conductor voltage exceeds the battery voltage, no current flows. Above this value, charging the capacitor C corresponds to charging the space charge. Note that the possible daily variation of corona is greater than the discrepancy between the loss curve which it is desired to represent and its analog. Thus the analog is sufficiently accurate for practical calculations of corona effects on power systems. Typical wave shapes of line-charging current including corona, as determined on the Anacom, are shown in Figure 14(B). Figure 15 shows transient voltage wave forms taken when de-energizing the line with and without corona, showing the magnitude of the effect and the consequent value of the analog.

Conclusions

Analog computer work is admittedly still in its infancy and the only conclusion that seems indisputable is that this is a very powerful method of computation of a wide range of complex engineering problems and a method which is quite rapid and flexible in its application. Other than this, our conclusions are simply a summary of some of the important points of the paper.

1. The direct-analog technique has distinct advantages in engineering design and application problems and has been used almost exclusively on the Anacom.

2. The sigma amplifier technique with consequent operation of all electronic equipment grounded is a major improvement in the direct-analog method. It simplifies problems of shielding and power supply, largely eliminates transformers and systematizes analog procedures.

3. The adjustable nonlinear resistor device is the preferred arbitrary function of a dependent variable provided the function to be represented is monotonic. Square-law representation within ±1 per cent is possible with five line segments, ±2 per cent with three segments, and ±5 per cent with two segments.

4. For other single-valued functions and certain double-valued functions the Photoformer presents a very useful solution. The ability to retain templates of important functions for subsequent use is of considerable value.

5. Studies of nonlinear systems have included representation of lightning arresters, transformer saturation, saturable reactors (magnetic amplifiers), saturation in machines, lubrication (fluid flow), hysteresis, corona, backlash (dead zone), limiting action, and other phenomena. Some of these have involved partial differential equations solved by the difference equation method. In this nonlinear field, computation by other means is extremely difficult and the analog computer is opening up vast new fields of information.

Table I. Analogous Relations in Speed Regulating System of Figure 3

Quantity in Actual System	Description	Analog
T_3	Mechanical time constant, $\frac{RI^*}{bg}$	R_3C_3
T_1	Rototrol time constant	R_1C_1
T_2	Exciter time constant	R_2C_2

Design and Control of Ferroalloy Furnaces

F. V. ANDREAE
ASSOCIATE AIEE

FERROALLOY furnaces form a special group of electric furnaces in which the electrodes are buried in the charge instead of standing over a bath of molten metal as they do in the steel-melting furnaces.

The main part of the energy is used to perform chemical reactions, such as the reduction of ores and the subsequent combination of the resulting elements with iron or other elements such as carbon.

Among their most important products are ferrosilicon, high-carbon ferromanganese and ferrochrome, silico manganese, calcium silicide, ferro phosphorus, and calcium carbide.

In contrast to steel-melting furnaces, ferroalloy furnaces are stationary. However, recently it has been proposed to install the furnace on a table which rotates very slowly around its vertical axis. The idea behind this invention is to avoid any freezing of the charge at any place of the furnace.

Electrically, ferroalloy furnaces are built for one, two, or three phases, see Figure 1.

Single-phase furnaces are either of the 1- or 2-electrode type. In the 1-electrode type, the current returns through the bottom of the furnace. In the 2-electrode type, the two electrodes are in series and the current passes from one electrode to the bath and from there to the other electrode.

Electrically, single-phase furnaces with return through the bottom are very simple. They have been developed in sizes up to 15,000 kw. In this case the return circuit is divided into several parallel branches distributed around the circumference of the furnace to reduce the reactance.

Two-phase furnaces may have two or four electrodes. They are not very frequent because they require special Scott-connected transformers and have no special advantages over the 3-phase type.

The 3-phase type is the one found most frequently, at least in the United States. It has three electrodes arranged either in line or in triangle. By combining two furnaces in one tank it can be designed with six electrodes.

The great majority of ferroalloy furnaces are open on the top, and the raw material is charged around the electrodes either by hand or by means of chutes fed from overhead bins and controlled from the furnace platform.

If the gases have a potential value, the furnaces can be provided with a roof and the vapors collected in suitable mains.

This is the case for ferrophosphorus furnaces where a part of the phosphorus, instead of being combined with iron, is volatilized and collected either as phosphorus or as phosphoric acid. In certain cases, also, the carbon monoxide resulting from the reduction of the ore is collected and used either as a fuel or as the starting point of various chemical compounds.

In size, ferroalloy furnaces range from a few hundred to 50,000 kw.

A furnace installation consists of the transformer, bus bars, flexibles, electrodes and holders, furnace, and collecting and controlling equipment, Figure 2.

A short description of the various parts of the installation will help in discussing design and control procedure.

Transformer

Transformers must be designed individually for the job. While the primary voltage is fixed by the power company, the low voltage must be specified by the customer from his own experience. Each product requires a special voltage which also depends upon the size of the furnace. On account of the unavoidable variations in the primary voltage and in the secondary due to the demands of the furnace, taps must be provided above and below the specified voltage. These taps are installed on the primary side. In general, tap changes are made with the load off, and the tap changers are of relatively simple construction.

Since the secondary voltage is low, very heavy currents must be handled in the conductors which result in tremendous forces acting between them. Coils and leads must be braced carefully.

Since the reactance of the bus and electrodes is relatively high, the impedance of the transformer must be made as low as possible.

The arrangement of the low-tension terminals is generally specified by the customer to fit the design of his bus bars.

Bus Bars

The bus bars form the stationary link between transformer and electrodes. In order to carry the heavy current with as little voltage drop as possible, the reactance of the bus bars must be low. Their design is a nice problem which requires considerable experience.

To reduce reactance as much as possible, outgoing and incoming conductors of the same phase are laid close together. On account of the heavy currents, the circuits are divided into several parallel branches. All these branches bundled together have led to the name "interlaced" bus. This interlacing is carried as far as possible and stops at the flexibles which

Y., January 30–February 3, 1950. Manuscript submitted May 13, 1948; made available for printing December 7, 1949.

F. V. Andreae is with the Southern Ferro Alloys Company, Chattanooga, Tenn.

Figure 1 (left). Single and 3-phase furnaces

Figure 2 (above). Typical ferroalloy furnace

are placed as close to the furnace as heat permits.

In 3-phase furnaces where the electrodes are in line, it is impossible to make all three reactances equal. This is due to the delta connections and the fact that the noninterlaced portion of the leads are more or less in the same horizontal plane. This inequality in the three reactances is the cause for the well-known dead phase. An easy way to explain the dead phase is by means of the following reasoning. If three conductors are in the same plane, the mutual inductance of the two outside conductors in relation to the center one are equal and larger than the mutual between the two outside conductors in relation to each other. A certain and considerable amount of power passes from phase 1 to phase 2 in the center and the same amount from phase 2 to phase 3, a much smaller amount however returns from phase 3 to phase 1. These amounts are in direct proportion to the mutual inductances.

It follows therefore that, if all three phases receive equal amounts from the transformer, phase 1 will deliver considerably less power at its extremity than phase 3, and phase 2 will deliver an amount half way between phase 1 and phase 3. Phase 1 is the dead phase.

This phase can be recognized easily by the smaller amount of raw materials it consumes and by the slower consumption of electrodes. If the currents are maintained equal in the three phases, the three tip voltages will be different: low in phase 1, average in phase 2, and high in phase 3.

To equalize reactances, the electrodes are arranged in a circle and the bus so designed that the noninterlaced parts of each phase are exactly alike. This involves more copper, but results in a balanced furnace and also in a better power factor, with a saving in losses because the currents are proportionally smaller.

Flexibles

Since the furnace loads are controlled by moving the electrodes up and down, a flexible member must be inserted between stationary bus and moving leads. Several methods are used to provide the necessary flexibility. Those most frequently used are copper cables designed especially to give maximum flexibility. In many cases the cables are water cooled which permits placing them closer to the furnace and reducing their number. Bundles of thin copper strips sometimes replace the copper cables.

Either strips or cables must be relatively long in order to permit the necessary up and down travel of the electrodes.

To shorten the path of the current, a swinging bar with short flexibles on one end and a rotary contact on the other end would reduce the reactance. It is difficult to design a satisfactory rotary contact for large currents. When the cables are water cooled they can be carried directly to the electrode holder through the hot gases of the furnace.

Electrode Holders or Clamps

The holder transmits the current from the copper leads to the electrode. Besides this it must carry the weight of the electrode and keep it from slipping. Holders are naturally water cooled. Each furnace designer has evolved some special type, and it is probably in this part of the installation that most ingenuity is displayed.

Electrodes

The electrodes carry the current into the reaction zone where the temperatures are extremely high, in the order of 2,000 degrees centigrade. There is only one material, namely carbon, which possesses all the necessary characteristics. It is a good conductor of electricity and is chemically resistant at the highest temperatures. Electrodes in most ferroalloy furnaces are made of amorphous carbon, prepared from anthracite coal, tar, and pitch and subsequently baked. Graphite electrodes are used only when particularly pure products are desired and where the ash content of the amorphous carbon electrode would be too high. The reactions in the furnace consist principally in the reduction of some oxide by means of carbon which is charged into the furnace in the shape of coke, coal, or charcoal. It is inevitable that the electrodes also take part in the process to a certain extent. Even if this consumption is small in comparison with the consumption of the normal reducing agents in the charge, the cost is high because the price per unit of carbon is very much larger in the electrodes. It is about 10-to-1 for amorphous carbon and 20-to-1 for graphite. There is, therefore, a serious economic factor in favor of the choice of amorphous carbon.

Instead of ready-baked electrodes, use is also made of so-called self-baking electrodes. This type of electrode, known under the name of their inventor, Soederberg, consists of large metallic

cylinders of the desired diameter in which green electrode paste is dumped. The heat of the furnace does the baking. The cost of green paste is much lower than the cost of prebaked electrodes, but the installation costs are somewhat higher.

Electrodes are suspended from the superstructure by means of cables or chains leading to electric winches or hydraulic motors which control their movements.

Furnace

The furnace is simply a large crucible, generally of carbon, built of cut blocks or formed with paste. In some cases the ore used in the process is used for the crucible, for instance in the manufacture of ferrochrome or calcium carbide. When carbon is used it must be backed by refractory brick in order to keep the heat from escaping.

The amount of heat insulation depends upon the viewpoint of the designer, his knowledge of the process, and of the existing temperatures. There is a balance between the costs of insulation and the amount of power saved. Even with an infinitely large amount of insulation, there will be losses, because though the temperature difference between shell and surrounding atmosphere becomes infinitely small the area is infinitely large.

Collecting Installation

The liquid product which is tapped at regular intervals is led into tapping beds or tapping cars which are made of various materials, depending on the product, such as cast iron, sand, graphite, or copper. If valuable gases are generated, the furnace is covered and the gas led to collecting tanks through suitable gas mains.

In a typical ferroalloy furnace, there is a deep crucible into which dip suitably-placed electrodes around which the raw materials are charged either by hand or by means of chutes fed from overhead bins. While the raw materials descend slowly they are preheated by the rising gases and the heat generated in the electrode. At the tip of the electrode, where the highest temperature exists, the reaction takes place. The liquid products collect at the bottom of the furnace while the gases seep through the charge and escape on top of the furnace. The change in volume is worth mentioning. From one pound of ore and half a pound of carbon which occupy together something like 0.014 cubic feet one-half pound of metal and one pound of carbon monoxide is obtained. At the reaction temperature this pound of gas occupies, at standard pressure, about 100 cubic feet. It is, therefore, necessary for the charge to be quite porous to permit these enormous amounts of gas to escape rapidly without creating too much pressure. While the speed of the raw materials is figured in feet per hour that of the gases is given in feet per second.

The temperature of the electrode plays an important part in the energy balance of the furnace. In an infinitely long electrode entirely exposed to the air the heat generated in the resistance will be dissipated along the cylindrical surface. The higher the current, the higher the temperature. This temperature, which is determined by the heat transfer coefficient to the atmosphere, limits the carrying capacity of the electrode. It must stay below the point at which the electrode will burn in air. The condition applies approximately to the part of the electrode above the charge. Below the charge the electrode is in presence of the charge whose temperature increases with the depth. In order to dissipate heat the electrode must be hotter than the surrounding materials; the coefficient of heat transfer determines the temperature difference between electrode and charge. It is evident that the temperature of the electrode increases with the depth and also with the length, and also depends on the temperature existing at the point where the electrode enters the charge and on the current, see Figure 4.

The temperature at the tip of the electrode varies with its position. It determines in large measure the temperature of the reaction because it represents the starting point at the hearth level. We see that a change in electrode position, if of long enough duration, affects the energy balance in the furnace.

The current that leaves the electrode passes through the surrounding narrow zone which acts as a resistor in which the electric energy is transformed into heat energy. Before this is done the energy is useless. From this small zone which is the heart of the furnace the energy radiates and does its useful work. There is a beautiful balance between furnished and consumed energy which is easily upset.

Electrical Characteristics of Furnace

Basically the furnace is an electric circuit with constant reactance and variable resistance. The reactance is determined by the characteristics of the transformer and the design of the bus bars including electrodes. Unfortunately for the operator, resistance and reactance are not far apart.

For rectangular furnaces the reactance at 60 cycles increases from around 0.001 ohm per phase for a 2,000-kw furnace to about 0.0014 ohm for 8,000 kw (not including the transformer). On the other hand the resistance decreases from about 0.0025 to about 0.0012 for 8,000 kw.

It becomes evident that for large rectangular furnaces the reactance becomes larger than the resistance. If the power factor is to be above 85 per cent the

Figure 7 (right). Operating equations

size of rectangular furnaces is limited to about 4,000 kw. In some cases such as phosphoric acid where R is high, the limit is higher.

Round furnaces can be designed with much lower reactance. This is true because the leads between the end of the interlaced bus to the electrode can be made shorter and because the delta is closed at the electrode instead of being closed at the end of the interlaced bus. See Figure 3.

In the calculation of electric furnace circuits the following set of equations has been found very useful. See Figure 7.

The maximum power input, W_{max}, into the furnace is reached when $R = X$ and is equal to $E^2/2X$, if E is the low-tension voltage between phases at no load. The actual power input W is equal to $W_{max} \sin 2\phi$.

The maximum possible current, I_{max}, is $E/X\sqrt{3}$.

The actual current

$$I = \frac{E}{Z\sqrt{3}} = I_{max} \sin \phi$$

$$\text{Cos } \phi \text{ is equal to } \frac{R}{Z} \text{ or } \frac{\text{kilowatts}}{\text{kilovolt-amperes}}$$

$$\text{Tan } \phi = \frac{X}{R}$$

By means of these relations it is easy to determine any desired unknown from given values. All that is necessary is a table of functions containing cos ϕ, sin ϕ, tan ϕ, and sin 2ϕ. See Figure 8.

For instance, knowing the reactance of a furnace and the voltage between phases, we can figure the power at which the power factor will be, say, 85 per cent.

We find in our table that for cos $\phi = 0.85$, sin $2\phi = 0.89553$, therefore $W = 0.89553\ E^2/2X$.

For cos $\phi = 0.85$, sin $\phi = 0.52679$, therefore

$$I = 0.52679 \frac{E}{X\sqrt{3}}$$

Another problem is to find the power factor of a furnace, at constant load, under varying voltage, either due to change of tap or change in the primary line voltage.

In this case we calculate a series of values of sin 2ϕ by dividing $2XW$ by E^2. The corresponding values of cos ϕ give the desired power factor.

If E becomes low enough the value sin 2ϕ is larger than 1 which is an impossibility. With sin $2\phi = 1$ we have reached the point of maximum power input. Without the table such calculations would be extremely tedious.

Design of Electric Furnaces

In designing a series of furnaces of various capacities for the same product one is interested in knowing the diameter of the electrode, the current, the voltage, the power input, and the size of the crucible. Of all these elements the size of the electrode is the only factor which varies in steps. The standard diameters of amorphous electrodes are 17, 20, 24, 30, 35, 40, and 45 inches. It is therefore logical to design a series of furnaces around their electrodes, see Figures 5 and 6.

An electrode of given diameter will only carry a certain current which is determined by the maximum allowed temperature of the surface.

If the energy generated above the charge as I^2R is in equilibrium with the energy dissipated along the surface

$$K(t_e - t_a)\pi DL = \frac{4\rho L}{\pi D^2} I^2$$

K = heat transfer to the atmosphere in watts per square inch degree centigrade

Figure 6. Relations between electrode diameter, voltage, current, and power input

Figure 8 (above). Trigonometrical relations

Figure 9 (right). Power input and current for varying voltage

t_e = temperature of the electrode surface in degrees centigrade
t_a = temperature of the atmosphere in degrees centigrade
D = diameter of the electrode in inches
L = length of the section in inches
ρ = resistivity of the electrode in ohms per inch per square inch
I = current in amperes

Above a certain temperature the electrode burns in contact with the air so that t_e cannot exceed a certain limit. For a given value of t_a, K and ρ are constant, so that the formula becomes

$$D^2 = b^2 I^2 \quad \text{or} \quad I = D^{3/2}/b$$

For very long electrodes, such as the ones in closed furnaces, the value of t_e must be chosen relatively low, otherwise the temperature at the tip becomes abnormally high. See Figure 4.

A 30-inch electrode which in ordinary furnaces will carry 30,000 amperes was found to be good for only 19,000 amperes in a furnace where the electrode extended ten feet under the roof.

In normal cases, the value of b^2 is around 30×10^{-6} when D is in inches and I in amperes.

Experience shows that in a series of furnaces making the same product with the same raw materials the resistance between electrode tip and furnace bottom multiplied by the electrode diameter is a constant. This comes back to the statement that the resistance per unit width of electrode circumference is a constant.

$$R \pi D = \text{constant}; \quad R = c/D$$

The value of c will depend upon the product and the raw materials used.

With these two equations we can calculate the voltage to neutral E_g and the power input per phase W_{ph}.

$$E_g = IR = \frac{1}{b} D^{3/2} \frac{c}{D} = \frac{c}{b} D^{1/2}$$

$$W_{ph} = I^2 R = \frac{D^3 c}{b^2 D} = \frac{c}{b^2} D^2 \text{ in watts}$$

For a 3-phase furnace the power input in kilowatts is $\frac{3c}{b^2} \frac{D^2}{1{,}000}$

Considering that the energy flows from the electrodes along the radius of concentric circles it is logical to assume that the active zone around an electrode will be circular with an area proportional to the power input, and since the power input is in direct proportion to the square of the electrode diameter the radius of the active area will be directly proportional to the electrode diameter. A good rule is to assume this active radius equal to the electrode diameter.

We now have determined all the factors necessary for the design of the furnace. The thickness of the lining will be chosen with the idea of making the sum of the cost of losses and amortization a minimum. In choosing refractories, care must be given to the temperature which they can stand. The next step is to design a suitable set of bus bars and leads.

From this design one can calculate the reactance and resistance per phase between transformer and electrode tip and finally the phase voltage at the transformer terminals. Several taps above and below the theoretical value will be specified to take care of variations in the primary voltage and requirements of furnace operation.

The type of bus bars will depend upon the size of the furnace and the specifications regarding power factor. For a small furnace a layout as shown on the left of Figure 3 will be satisfactory; for a large furnace, 6,000 kw or more, it will be necessary to use an arrangement such as indicated on the right with the delta closed at the electrode holders.

Control of Furnaces

Many factors affect the operation of the furnace. The raw materials must have the proper analysis and be of suitable size; they must be mixed in the right proportion. Their speed must be constant so that they reach the crucible without interruption. There they must find the right temperature and the correct current and voltage.

If one of these factors is wrong, operation is spoiled. The duty of the operator is to diagnose the trouble correctly and to apply the proper remedy. The outward sign of a disturbance is generally a change in the electrical conditions.

In order to be able to see what is going on the operator has before him a panel with ammeters, voltmeters, and wattmeters, and generally a recording wattmeter, which provides a record of the furnace's operation. He also has in front of him an indicator showing the position of the electrode in relation to the furnace hearth.

The fundamental relation which governs the control of the furnace is $I = E/R$, where E is the voltage between electrode tip and furnace bottom, I the current, and R the resistance of the circuit between tip and bottom. The value of R is not exactly known. It decreases when coke is added and it increases when the electrode rises but not uniformly.

Everything seems to indicate that the largest part of the voltage drop takes

place in a very small zone around the electrode tip. The circuit is a pure resistance. Oscillograms have shown that it does not contain any higher harmonics to an appreciable degree.

The most important factor which affects operation is R. E also is liable to vary. I is only indirectly affected.

Changes can be due to outside influences or to a variation in the operating conditions of the furnace.

In general E is assumed to be constant. Any change in R will bring a change in I in opposite direction.

From the fact that a change in I is an indication of the disturbance, the current is used as the main control in automatic regulation.

The regulators try to keep the current constant and do this by controlling the movements of the winch motors. In the simplest kinds of regulators this is done by means of contactors; in more recent regulators the current circuit passes through an amplidyne set mounted on the shaft of the winch motor. As long as the current is normal the motor is quiet; if the current drops below normal the motor lowers the electrode, decreasing the resistance in the furnace and bringing I back to normal. If the current rises above normal the motor reverses and lifts the electrode.

In normal operation there are two reasons for change in R: the electrode is consumed in the furnace; and the path between electrode tip and neutral is shortened by the slow accumulation of metal between taps.

In both cases the regulator automatically takes care of the change in R and restores normal current.

If an electrode position indicator is used it must be adjusted to the electrode consumption which is known. An adjustment at the end of each shift is sufficient. When an electrode is slipped and the indicator is connected to the holder a corresponding adjustment must be made.

More irregular variations in R are due to changes in the mix, more especially in the coke distribution. If due to improper mixing the proportion of coke increases at the tip of the electrode, the resistivity of the resistor decreases and I increases. The regulator lifts the electrode. If the variation is only temporary, the regulator is kept in operation. The electrode will rise momentarily, later coming back to its normal position when the disturbance disappears. If the effect is lasting it might be necessary to operate manually for a while, at the same time reducing the coke in the mix, or charging raw mix around the electrode. A skilled operator knows from the behavior of the furnace how much is necessary.

If the mix has too little coke the electrode plunges into the furnace under the influence of the regulator. If the disturbance is lasting, manual operation and the addition of coke around the electrode might be necessary.

If the disturbance is lasting it can become dangerous because the electrode is liable to reach the bottom and tip over. This should not be allowed.

It also can happen that cold charge of high resistivity slips under the electrode. The regulator is unable to bring normal current. This is often the case after tapping when a hole is created under the electrode. In general, the regulator is disconnected during tapping time. In certain furnaces the recovery after tapping is so slow that regulators are not used at all and the furnace is operated entirely by hand.

If the voltage is constant a regulator controlled by the current will maintain constant power input.

The current can also change due to a change in the voltage. The change in E can come from a disturbance inside of the furnace. Even if the three delta voltages do not change the voltages to ground might vary considerably. The neutral may travel inside the triangle due to disturbance in the metallic neutral, but most changes in E are caused by variations in the primary voltage. These might be caused by changes in load distribution in the feeding circuit or by intentional variations; for instance, lowering of voltage at night when industrial customers are idle and rises in residence voltages must be avoided. These changes of voltage cause serious problems.

Since most contracts contain a demand clause, the operator tries to keep his load as constant as possible. When the primary voltage decreases the current must be increased. As long as the variations are reasonably small the equipment can take care of the increase in current. However, when the variations are large, two difficulties arise. The first one is an excessive heating of the bus and electrodes, the second is a decrease in power factor which at the limit reaches 0.707. At this point, the power input into the transformer is a maximum, and any current increase beyond this point results only in a decrease in power.

Some rather peculiar conditions have been observed, especially with inexperienced operators.

Referring to Figure 9, the line ABC represents conditions as the voltage decreases from 12,400 to 12,240 volts. C is the point of maximum power input. If the voltage decreases still further and the operator is unaware of the condition he might still increase the current reaching point D. There he stops and if the voltage goes down to 12,000, point D_2 is reached. Now the voltage starts to go up and the operator seeing the power go up keeps the current constant until normal power is reached at 12,280. Here he might become confused and with further increasing voltage might increase the current arriving at points E and perhaps F at which he has normal power with normal voltage, but at currents considerably in excess of normal.

To avoid such errors the operator can be furnished with a table giving him the highest current that he should carry at any time, in this case C'.

If the furnace plant is at the end of a long feeding line the voltage drop in the line increases the effect of a voltage drop at the substation. The station operator may think that his line is good and that the variations are small, but by the time they reach the plant they are greatly multiplied. To remedy this situation, a bank of capacitors will improve conditions and a voltage regulator at the plant will maintain constant voltage at the furnace transformer. Such equipment is very expensive, and since it is difficult to express the advantage of constant voltage in dollars and cents, it is hard to convince the management that it is necessary. The power company, however, may see the advantage of a capacitor in increased revenue from higher loads.

Many contracts contain a power factor clause, which states that the monthly demand (generally 30 minutes) will be adjusted for the power factor existing at the time of the demand. Under normal voltage conditions the power factor might be entirely satisfactory. If, however, at the time of the demand the voltage was low, the power factor might very easily be below the contract power factor and the consumer is penalized for a condition entirely out of his control. The power factor clause should contain an arrangement that it should be adjusted for the voltage.

The control of an electric furnace requires constant attention and long experience. The operator at the switchboard has a considerable responsibility because the proper running of the furnace depends on his reactions.

No Discussion

Electric Equipment and Operation of Graphitizing Furnaces

EDWARD R. COLE
ASSOCIATE AIEE

THE method of graphitizing amorphous carbon by accidently overheating silicon carbide was discovered by Dr. Edward G. Acheson. The silica was volatized out and pure carbon or graphite remained. A lubricant had been made from an abrasive material. His conclusions were that to produce graphite a carbide had to be made first and then reduced by heating. Subsequent tests showed that the purest form of carbon (petroleum coke) could be graphitized without adding sand.

Another theory exists today on the formation of graphite in the electric furnace. It is believed that pure carbon at about 2,600 degrees centrigrade has a better affinity for its like than for any other element and the pure particles of carbon combine to form a new material approaching the real density of themselves. Further proof is presented as objects shrink a very definite amount during graphitization. By the addition of enormous pressure to the graphite while at the temperature of 2,600 degrees centigrade, a pure white diamond has been made experimentally. The graphite changed from black to white and its physical properties from a lubricant to an abrasive.

Usual Process of Manufacture of Graphite Electrodes

The usual steps in the manufacture of graphite electrodes are to load the green, or pitch bound preformed electrodes, into a ring or other type of fuel-fired baking kiln, where they are baked to the amorphous or raw state, by heating slowly to a maximum temperature of 1,300 degrees centigrade. After they have cooled down to room temperature they are unloaded, inspected, and reloaded into an electric furnace for graphitizing.

Dow Process

Figure 1 illustrates the arrangements of graphitizing furnaces and transformers at the Dow Chemical Company. The greens are baked and then graphitized in the same furnace on a continuous run. This eliminates the backing kiln and the labor, to load and unload kilns, together with the necessary fuel to heat the material up to 1,300 degrees centigrade the second time. There is no raw electrode inventory or kiln and storage buildings. Five handlings are saved and time of production is reduced as much as eight weeks.

The baking is accomplished by a 400-kva tap-changing transformer in an Acheson-type resistance furnace. Interlaced secondary bus bars, in trenches, with proper switching arrangements, conduct the current from the 400-kva transformer to any furnace in its group. The switchboard attendant follows a predetermined schedule of temperature increase from room temperature to approximately 1,300 degrees centigrade, by changing the taps on the primary winding under load. This baking time may be as much as 200 hours, depending on the size of the electrodes and the weight of charge in the furnace. The secondary voltage is variable under load, between 40 and 120, with one interruption, to change the secondary switch from multiple to series-multiple position.

After the baking period, the 400-kva transformer is switched to another furnace and the 1,600-kva graphitizing transformer is moved into place and connected to the furnace. Before applying the load, however, all the thermocouples, used to indicate temperature while baking, are removed from the furnace. From 80 to 100 more hours are required to bring the temperature up to 2,600 degrees centigrade. The cooling period amounts to 85 hours or more before the graphitized electrodes can be removed from the furnace. Each 400-kva baking transformer serves four furnaces and each graphitizing unit requires two bakers or eight furnaces to keep it running full time.

The graphitizing transformer is rated 13,800 volts, 1,600 kva—40/80—40,000/-20,000 amperes, 60 cycles, with 16 steps on ratio adjuster. By means of a secondary switch the coils can be connected series-multiple, thus making the full voltage range 40/160 volts, variable by 32 steps of near equal value. The secondary winding has full 1,600-kva rating for all taps of the ratio control.

Operation Without Power Factor Correction

Operation at the Dow Plant was started without any power factor correcting device. It was found that when the secondary current rose above 20,000 amperes the power factor decreased rapidly until at 40,000 amperes its value was down to 0.41. The load had to be raised to 3,200 kva, to secure a kilowatt load high enough to produce graphitization. The secondary voltage reached 63 volts at this load. As the graphitizing transformers operate single phase, a very bad condition was set up at the power house and on the transmission lines, due to this overload and low power factor. However, the transformer was liberally designed and withstood the 100 per cent overload for a few hours, at the end of 50 runs, without overheating or otherwise being damaged.

Paper 50-97, recommended by AIEE Chemical, Electrochemical, and Electrothermal Applications Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted February 20, 1949; made available for printing December 6, 1949.

EDWARD R. COLE is with the Dow Chemical Company, Midland, Michigan.

Figure 3. Connections to portable side bars

Installation of Series-Capacitor Power-Factor Corrector

A series-capacitor transformer rated 2,200 kva with operating voltage on a primary winding of 40 volts and 2,420 volts secondary across the capacitors was installed. There are 140 individual capacitor units, each rated 15 kva at 2,300 volts. The total reactance value of this series capacitor is 0.0015 ohm. It does not produce full unity power factor as the total reactance in the secondary circuit, including bus bars, series transformer, and furnace, totals 0.00207 ohm.

The secondary terminal connections of all the transformers (400 kva and 1,600 kva) used in the process are brought out through the top of the case with alternate terminals of like polarity. This allows interlacing of the bus bars from transformer to the load. The connection of the series transformer into the furnace circuit is accomplished in the shortest possible distance and is a permanent assembly carried on the transformer truck. See Figures 2 and 3. As the graphitizing transformer can be brought to within five feet of the furnace head, the length of the secondary circuit is only 35 feet long, Figure 4.

Portable side bars are hung along the side of the furnace, as return circuit, for the graphitizing transformer, as shown in Figures 5 and 6. They are spread apart to envelope as much of the furnace surface as possible. This arrangement is the same for each furnace regardless of its location in the furnace room. Had the customary system of stationary graphitizing transformer been used, some 400 feet of bus, consisting of 32 1/2 inch by 6 inch copper bars or other bus bar metals, would have been required together with 16 switching stations of 40,000 amperes' capacity. The inductance and resistance thus added would have further reduced the power factor and efficiency of the secondary circuit below 0.41.

High Tension Power Supply

Single-phase power is brought from the switch room to the graphitizing trans-

Figure 2 (left). Permanent connection of series transformer

former in conduit, hung from the ceiling, for the full length of travel of each of the 1,600-kva graphitizing transformers, see Figure 1. A bayonet-type toggle-operated isolator switch is located at each furnace for connecting the graphitizer transformer to the 13,800-volt power line. The capacitor units are located in a room adjacent to the transformer bay. A bus extends from them full length of run of the transformer with which they are used, with terminal boxes in which flexible leads from a series transformer are connected. Doors to these terminal boxes and the operating handle of the isolator switch are interlocked with the transformer's oil switch to prevent its being closed until all contacts have been made. When the oil switch is closed the truck motor's circuit is blocked out to prevent the possibility of moving the truck while the transformer is furnishing power to a furnace.

Figure 6. One-line electrical diagram of graphitizing transformer circuit

Operation Control

Figure 6 is a 1-line electrical diagram of the complete circuit of a graphitizing furnace.

In Figure 7 is shown the control board. The control consists of an ammeter, voltmeter, wattmeter, and watt-hour meter in the primary circuit together with a Selysn tap position indicator. The only secondary intrument is a voltmeter. The secondary voltmeter and the wattmeter are indicating-curve drawing instruments. Each 400-kva baking transformer also has a 6-point indicating and curve drawing, automatic circuit changing, temperature recording instrument.

During the baking period the load is increased on a temperature schedule up to 1,000 degrees centigrade, at which point the thermocouples are removed from the furnace. Beyond that the load on the furnace is increased, according to a kilowatt load curve, as determined by experience, until 2,600 degrees centigrade is reached.

The 1,600-kva graphitizing units have in addition an ammeter in the secondary circuit. Its current transformer operates a relay that turns on a red light, when current reaches 38,000 amperes, to warn the operator; and also an overload relay which trips the oil circuit breaker if current is allowed to reach 40,000 amperes. Should the operator fail to reduce the load the circuit is automatically opened at this point to prevent oversaturation of the series transformer. Figure 8 shows a typical volt-ampere characteristic curve

Figure 9 (right). Current, voltage, and power factor versus running hours of graphitizing furnace

Run Number 47 (without capacitors), charge 37,900 pounds. Run Number 793 with capacitor, charge 43,000 pounds

of a transformer connected to a series capacitor. When the transformer current in the line reaches a maximum it begins to decrease as the rising saturation of the series transformer increases the effective capacitance ohms. The working range of the equipment is shown by the straight line and the maximum value of current is indicated where the curve turns.

Characteristics of Graphitizing Furnace

Some 50 furnaces were graphitized without power-factor correcting equipment. Figure 9 shows running conditions without and improvements obtained with a capacitor power-factor correcting device.

The curves for Number 47 (dotted lines) represent data from run without corrector. Run Number 793 (solid lines) shows improvements after installing series transformer.

Note particularly that in addition to improving the power factor from 0.41 to 0.77 the furnace charge has been increased from 37,900 pounds to 43,000 pounds. The secondary voltage also improved to such an extent that it is no longer necessary to change the secondary switch connection from parallel to series multiple; thus in a new installation the cumbersome 40,000-ampere series-parallel switch can be eliminated.

Experience has shown that an exact duplicate of this circuit, on 25-cycle power, gives a power factor of 0.85, without using series transformer for correction.

Changing Taps under Load

Tap changing under load is justified as changes on a graphitizer are made about twice an hour; 777 runs showed a total of 16,770 tap changes on the graphitizing transformers alone. The 400-kva bakers change taps more frequently. With six transformers in operation at once it would require several men to manually change taps. To do this the load would have to be taken off. When the power is discontinued for a short period, especially when the furnace has reached 1,500 degrees centigrade or above, excessive radiation starts.

The lost heat must be returned to furnace charge by supplying extra power to re-establish a progressive increase in the heating schedule.

Due to the fact that atmospheric conditions around the graphitizing transformers are extremely dusty, with large quantities of graphite dust settling on everything, junction box potheads were used on transformers for incoming cables. A special packing device of water repellent material was made around the secondary terminals to break the dust layer into vertical sections to prevent short-circuiting. The entire unit is washed down frequently to remove the graphite dust deposit, as blowing with compressed air still leaves the surfaces covered with a thin film of graphite.

Economics of the Series Capacitor

Had the operation been continued without the power-factor correcting device, a new 3,200-kva transformer costing $32,000 would have been necessary, as 1,500 kw is required at the end of graphitizing run. The transmission lines were too light, as were the oil circuit breaker and current transformers. Our new series transformer cost $22,000, giving a saving of $10,000 for that item. Referring to Figure 9, the operating conditions show a drop in load from 2,240 kw without series capacitor, and with power factor of 0.41, to 1,610 kw with a power factor of 0.77 at the end of runs Numbers 47 and 793.

When the 13.8-kv system with the transmission line, transformers, and turbines is considered, the cost of the series capacitor device is saved many times over each year. The lessening of the burden on the 13.8-kv system is difficult to evaluate. If only one graphitizer with two 400-kva bakers is in service, all running single phase, it is impossible to balance the load on each phase. Generating capacity equal to about three times the kilovolt-ampere load had to be supplied. With two 1,600-kva graphitizers and four 400-kva bakers the phase balance was improved. To operate all these transformers without correcting the power factor, the new equipment would have cost well over $150,000.

No Discussion

Electrode Control and Associated Operating Mechanisms

E. A. HANFF
ASSOCIATE AIEE

THE history of the development of the control or regulation of furnace electrodes has been interesting. In this paper, it is not intended to discuss the technical features of the various methods of control in use; as such details are covered quite ably and fully in papers presented by engineers engaged in the design and manufacture of such equipment.

Essentially, the electrode regulator is required first to establish arcs from the electrodes to the metal in the furnace and then to adjust the arcs to admit a uniform flow of power into the furnace under widely varying conditions at different phases of the melting process. Except for occasional manual adjustment of the voltage and rate of input; the control is fully automatic.

On the earlier furnaces, operating single phase, regulation by hand was not too difficult. With a 3-phase furnace, manual control is not practicable.

Before the advent of arc furnaces, automatic regulation of electrodes in arc lamps was in general use. With the small currents and light-weight electrodes, a simple solenoid in series with the arc balanced the weight of the electrode against the solenoid pull and provided very satisfactory regulation. The time lag between a demand for change in position and actual movement to the required position was very small, due to the direct linkage possible between the electrode and the solenoid armature.

In furnaces, an intermediate power-driven mechanism is necessary, of course, to move the electrodes. One of the principal problems in developing a satisfactory regulator is to control this power operated mechanism so that the electrode will be moved to its correct position with minimum loss of time and with the least amount of overtravel in either direction.

The Thury regulator was one of the earliest successful types. This regulator employed mechanically-operated contactors which energized the electrode motors in a series of impulses in either direction. This type was succeeded by the magnetic-contactor type, such as the Seede regulator, and by later modifications, including the well-known "balance beam" regulator which utilizes both current and voltage elements in the primary relay instead of current elements only.

Since the Thury and contactor types make use of primary relays or solenoids to energize the motor contactors, there is an appreciable time interval at each operation. This time lag makes the control more irregular than is desired with ideal control. With the introduction of rotary regulators applying variable voltage to the electrode motors; somewhat similar to the old Ward Leonard principle, the current and voltage fluctuations in the arc circuit are more directly applied to the electrode motor without the intervention of relays or contactors. Furthermore the speed and direction of rotation of the motors are controlled directly by these arc fluctuations. The electrodes therefore are moved more steadily in the required direction at a speed roughly proportional to the magnitude of the variation from the desired current value; instead of in a series of impulses as with the contactor type of regulator.

In order to present a comparison between the contactor and rotary regulators, comments and data obtained through the helpful co-operation of representatives of manufacturers and users of both types have been assembled. This information is given in Table I to show the advantages of the two types. Only the more important items are shown, although the table could be expanded to include many other features.

In certain installations it has been possible to get comparative data by operating the same or duplicate furnaces with both types of regulators. On one large installation equipped with switches for transfer from one type to the other, an average saving of 3 to $3^1/_2$ per cent in both time and power consumption, in favor of the rotary regulator, was observed. Because of unavoidable delays and variations in the charge and operating conditions occurring in different heats, it is impossible to obtain comparisons under identical conditions.

It is quite difficult to evaluate fully the savings in maintenance costs with the rotary regulator. In addition to the elimination of frequent adjustments and replacements for the regulator itself, the steadier operation of the motors, without

Figure 2. Notch and latch-type electrode safety stop

Figure 4. Details of tripper-bar operated clutch-type safety stop

the repeated starts and stops under dynamic braking, tends to reduce the maintenance costs on the motors and driving mechanism.

The remainder of the paper will discuss certain associated mechanisms which concern the operation of the furnace electrodes.

Most arc furnaces are operated by d-c motors geared to wire rope drums. For many years a combination of worm gear and open spur gears has been used, but recent preference has been for completely-enclosed gear sets, usually of the double-reduction worm type.

Figure 3. Shop view of clutch-type safety stop in holding position

Since all wire rope has a certain amount of elasticity, it is desirable to keep the rope length to a minimum so that the rope stretch will not affect the accuracy of control unduly. This effect is less noticeable with the rotary regulator because of the smoother acceleration and deceleration.

Hydraulic cylinders are in use to some extent in place of motors, particularly in European practice. Hydraulic drives have their peculiar advantages and disadvantages; but since the extensive adoption of the rotating regulators, there appears to be less interest in the use of hydraulic equipment for electrode operation.

In handling electrodes by means of hoisting ropes, it is advisable to provide means to prevent damage from overtravel. The upward movement is limited by the height of the masts which support the electrodes. In the lowering direction, if the moving structure reaches the limit of travel, or if the electrode comes to rest on solid scrap in the furnace with little or no flow of current, the hoist rope will become slack or unwind from the drum. To prevent damage or delays resulting from such overtravel, limit switches are often used. Figure 1 shows these switches as mounted at the top of the masts. The switch at the left stops the upward travel when the moving crosshead lifts the vertical rod to engage the hatchway switch lever. In the slack cable switch at the right, the hoist rope is anchored to the guided member at the top of the heavy compression spring. The weight of the electrode system normally compresses the spring and the limit switch contacts remain closed. If the electrode is prevented from moving down for any reason, the

spring releases and the contacts open.

Under normal conditions, the electrode hoisting ropes give long service, but, as with any wire rope, they will wear out eventually or may be damaged from some unusual occurrence. When a rope fails, the electrode and its supporting arm will drop and may damage the electrode arm or the furnace roof. If it only breaks the electrode, delay and expense may result because of the labor required to remove the broken pieces and from contamination of the molten metal with excess carbon.

The best insurance against such accidents is to maintain close inspection of the ropes and replace them before they reach the danger point. As an additional safety feature, furnaces now are being equipped with a device which prevents the electrode arm from dropping even if the rope fails.

One of the first devices of this description is shown schematically in Figure 2. In this design a steel latch is mounted on the movable crosshead and arranged to travel in line with a series of notches built into the mast structure. The latch is held out of engagement with the notches by means of a solenoid, the coil of which is energized through contacts of the slack cable switch. In case of a rope failure, the slack cable switch opens the solenoid circuit, releasing the latch, which engages the nearest notch in the mast. The crosshead is brought to rest immediately and is safely held until a new rope can be installed. As an improvement on this design, eliminating the electric solenoid, the friction clutch or sprag arrangement shown in Figure 3 was developed. In this design a vertical round rod, serving as a brake member, is mounted on the mast structure parallel to the vertical axis. A tiltable clutch member, carried on the crosshead, is provided with a hole slightly larger than the brake rod which passes through the hole. Figure 4 shows the construction more clearly. The clutch member normally clears the brake rod, but upon failure of the cable, the mechanism causes the clutch to tilt sufficiently to grip the sides of the brake rod. The action is so rapid and positive that the crosshead is stopped before it has accelerated appreciably, thus limiting the shock. Since the movement is stopped by friction, there is a small amount of slipping and the stopping is not as abrupt as with the notch and latch type just shown. It has been found, however, that the device will stop a large crosshead with a heavy electrode within a small fraction of an inch.

Table I. Comparison of Contactor and Rotary-Type Regulators

	Contactor Type	Rotary Type
Performance		
General performance	Satisfactory	Excellent
Smoothness of operation	Somewhat rough	Very smooth
Arc and overload power interruption	Frequent	Infrequent
Motor resistor power losses	Yes	No
Motor generator set stand-by losses	No	Yes
Kilowatt-hour energy consumption	100 per cent	94–99 per cent*
Total time of heat	100 per cent	91–95 per cent*
Electrode consumption	100 per cent	95–100 per cent*
Maintenance		
Complexity of control system	Quite simple	Rather complicated
Diagnosis and correction of trouble	Easily located	More obscure
Inspection and adjustment	Frequent	Seldom required
Spare part requirements	Inexpensive parts	Spare motor generator set
Rotating machine maintenance	Motors only	Motors and motor generator sets
Type of supervisory personnel	Average	Highly skilled
Cost Comparison		
Regulator only, 100 to 5,000 kva	100 per cent	150–165 per cent*
Regulator only, 6,000 to 12,000 kva	100 per cent	180–190 per cent*
Total furnace cost, 100 to 5,000 kva	100 per cent	103–101 per cent*
Total furnace cost, 6,000 to 12,000 kva	100 per cent	101–100.7 per cent*

* Approximate averages based upon figures supplied by several sources.

Figure 5. Clutch-type safety stop operated by pivotted sheave

In a modification of the design, shown in Figure 5, a different method of tripping the clutch is employed. In this arrangement the sheave on the crosshead is mounted in a pivotted cradle. Normally, the weight of the electrode system keeps the sheave and cradle in a vertical position. When the rope breaks, a powerful spring tilts the sheave cradle and a connecting link to trip the clutch member. This arrangement, being simpler and having fewer parts is preferred over that shown in Figure 4.

In order to meet the increasingly important demand for furnaces and equipment which will produce more output with less labor and material, the furnace and electric equipment manufacturers must be alert to develop new devices and improvements in existing designs. In this brief discussion it has been possible to describe only a few of these developments.

Discussion

J. R. Lee (Pittsburgh Lectromelt Furnace Corporation, Pittsburgh, Pa.): Mr. Hanff has presented an interesting paper on several phases of arc furnace design and operation. We would like to point out several things that should not be overlooked in considering electric furnaces as a whole.

As brought out in this paper, it is true that 3-phase arc furnaces require automatic electrode control almost invariably unless they happen to be of a character such as electro-smelting furnaces used on charges and processes where the resistance changes very slowly. For many operations a very much simplified control is justified from an economic point of view.

The statement by the author is correct to the effect that the relay-type regulator is lower in first cost, but requires more regular adjustments as the contacts wear away than does the motor-generator (or so-called rotary-type) regulator. While the rotary-type regulator requires less frequent adjustments and repairs, trouble shooting requires more highly skilled attention and the supply parts and repairs are of a more expensive type. We have found it advisable to stock a complete spare motor-generator unit in addition to various resistors and rectifiers which can fail for a number of reasons. It has been our experience that when the relay-type regulators are in proper adjustment, the operating results are practically as good as with the rotary-type regulator. In fairness, we should add that it is sometimes very difficult to impress the average maintenance man with the advantages to be gained by proper setting of the regulator. Reports indicate that wear and tear on the winch motors, electrode supporting gears, rams and sheaves is slightly less with the rotary-type regulator.

The rotary regulator built according to standard design is very well adapted to use on steel-type furnaces where the load is of a very highly fluctuating nature. There is reason to doubt that it does as good a job as the contactor-type on bare bath, submerged arc, or deep slag operations unless its standard design is considerably modified.

The author discusses several schemes for preventing drop of arms in case of cable breakage. These are of the well known safety stop type which have been in use on elevators in various varieties for many years past. However the height of the lift of the electrodes is so small, the danger to human life so remote, and the liability of drop so very infrequent, that the vast majority of furnace men feel that proper inspection of the cables is a better substitute.

It is proper to note that with the counterbalanced electrode cable drive and the so-called friction-bite attachment of the cable to the drum, that the limit stops for both up and down travel are eliminated entirely and thus the arm travel is held, by the friction bite scheme, within safety limits to a small fraction of an inch.

The paper discusses the elasticity of the hoisting cables. Our experience has not indicated even the slightest difficulty due to such cause where the electrode arms are properly mounted on truly machined masts, fitted with hardened rollers and running on antifriction roller bearings. In other words the difficulty seems to be purely theoretical and with little if any effect on the practical performance of the furnace.

E. A. Hanff: In his discussion of this paper, Mr. Lee points out that in certain types of operation, the contactor type of electrode regulator may give results that are as good as, or better than, the rotary type. This is true and it was not intended to give the impression that the rotary type should entirely supersede the contactor type. However, the rotary type has received wide acceptance, particularly on large melting units. Even on smaller units, where the actual operating costs show little or no saving and where the proportionate initial cost is much greater, there has been a marked preference for the rotary type. Perhaps this preference is partly psychological owing to the unobtrusive, smooth performance of the rotary regulator as compared with somewhat noisy and jerky action of the contactor type.

The friction-bite attachment mentioned by Mr. Lee is an adaptation of an old principle used widely in hoisting and haulage equipment. As applied to hoists, such as furnace door hoists, the drum and counterweight can be mounted close to the load with a minimum of guide sheaves and with short cable length. On an electric melting furnace, the hoist drum and counterweights are usually mounted away from the furnace, resulting in rather long cables and a complex system of guide sheaves.

Contrary to Mr. Lee's experience, we have found that the elasticity of the hoisting cables has a noticeable effect. Tests made by one of the regulator manufacturers demonstrated that the momentary stretch or "bounce" is measureable and has an appreciable effect on the magnitude of the instantaneous current peaks. This effect would be less noticeable where there is enough friction in the sheaves or electrode arm system to "damp out" the bounce.

It was pointed out in the paper that maintenance of close inspection of the hoisting ropes is the best insurance against cable breakage. However, such maintenance is sometimes lacking and there is an occasional accident. Recently, we had a case where a workman carelessly held an acetylene torch flame near a hoist rope, burning it in two. The safety device prevented the electrode arm from dropping and, in this case, may have prevented physical injury. The elimination of possible mechanical damage to electrode joints, electrode arms, and roofs is the feature of the device that has been most appreciated by operators who have become familiar with it.

Impulse Measurements by Repeated-Structure Networks

C. L. DAWES
FELLOW AIEE

C. H. THOMAS
ASSOCIATE AIEE

A. B. DROUGHT
STUDENT MEMBER AIEE

SURGE testing of dielectrics and electric apparatus with impulse voltages having steep-wave fronts has recently become important and has necessitated a much higher degree of accuracy in the measurement of such impulse voltages. It is the purpose of this paper to show that repeated-structure networks are ideal in principle for any type of surge-voltage measurement. Experimental study of prototype networks and tests on a larger-scale model indicate that it is possible to make this type of measurement with a high degree of accuracy. The repeated-structure network has a realizable characteristic impedance termination that is the same for all frequencies. This characteristic impedance is of such form that the input impedance of the cathode-ray oscillograph may be part of it. There will then be no reflections and a wave of any form whatsoever impressed upon the network will be reproduced exactly, though attenuated in amplitude, at the input terminals of the cathode-ray oscillograph. Furthermore, the repeated-structure feature makes it possible to construct this network of such length that the need for a cable lead per se between the voltage divider and the oscillograph is eliminated. The paper discusses briefly the present methods of high-voltage measurement pointing out the limitations and the disadvantages of the dividers now in use.

Present Potential Dividers

F. M. Defandorf has summarized the methods of high-voltage measurement.[1] Of the various methods, the potential divider is used widely for the measurement of impulse voltage. Present voltage dividers may be divided into four groups: corona-shielded resistor; surge resistor; capacitor divider; and capacitance-shielded and guarded resistor.

The corona-shielded resistor tends to increase stray capacitance and for this reason is undesirable. At the present time the surge resistor type of divider shown in Figure 1 is commonly used. This consists of a large number of resistors bifilar wound on cards, all connected in series. A voltage tap across a portion R_a of the grounded end of the resistor is connected to another voltage divider R_b usually through a considerable length of shielded cable. The cathode-ray oscillograph is connected to the tap of the voltage divider R_b. This arrangement is identical with that shown in Figure 1 of reference 2. The AIEE standards state that R_a is optional. It appears, however, that inclusion of R_a would be desirable in order to reduce reflections from the sending end of the cable.

It is apparent from previous investigations[3,4,5] that a surge resistor divider cannot be represented as a lumped pure resistance parameter. Since it is not a pure resistance, errors in the reproduction of wave forms may be expected. A surge resistor divider can be more accurately represented by the circuit in Figure 2 where, R_g is the leakage resistance to ground; R is the series resistance; C_s is the shunting capacitance between turns; C_p is the parallel capacitance to ground; and L is the series inductance. Böchman and Hylten-Cavallius[4] presented an analysis of the errors involved when such an equivalent circuit was used. In their analysis, when the error due to any one element was examined, all others were neglected. The combined error of the several elements was not taken into account.

Preliminary to the study of the voltage divider described in this paper an investigation was made of the surge-resistance card type of divider. This consisted of 10 bifilar wound cards as elements, each having a resistance of 500 ohms. The several parameters shown in Figure 2 were determined by appropriate measurements.

As will be shown later, there was a substantial phase displacement between the input and output voltage, when the applied frequency became high.

In an attempt to minimize the effect of inductance and extraneous capacitance, the capacitor type of divider is sometimes used.

The usual circuit arrangement for a capacitor divider is shown in Figure 3. This consists of a single high-voltage capacitor in series with a ground capacitor of low-voltage rating. It is extremely difficult to compute the divider ratio even when the capacitance of the units are known, since when high-voltage capacitors are used, large spacings are involved, and the capacitances to ground may be as large or larger than the capacitance between the two electrodes of the high-voltage capacitor. J. H. Hagenguth[6] points out that in laboratories where capacitor dividers were used rather extensively, it was found necessary to calibrate the divider with an auxiliary resistor divider. Furthermore it is difficult to connect the cathode-ray oscillograph in a satisfactory manner to a capacitor divider. A cable lead with resistance termination

Paper 50-89, recommended by the AIEE Instruments and Measurements Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted September 19, 1949; made available for printing December 5, 1949.

C. L. Dawes is Associate Professor and C. H. Thomas is Instructor of Electrical Engineering at Harvard University, Cambridge, Mass. A. B. Drought is Assistant Professor of Electrical Engineering, Marquette University, Milwaukee, Wis.

The authors wish to thank J. H. Hagenguth of the High-Voltage Engineering Laboratory of the General Electric Company at Pittsfield, Mass., for suggesting the voltage divider as a problem for this research performed in partial fulfillment for the degree of Doctor of Science by A. B. Drought. We appreciate the loan by Mr. Hagenguth of a wire-wound resistor card which became the basic unit in the surge-resistor type of divider which was constructed. We also are indebted to F. L. Bellaschi who followed the research closely and recommended a presentation of this work.

Figure 1. Surge resistor voltage divider

is undesirable, since this tends to prevent the voltage across the low-voltage capacitor from following the wave form of the impressed voltage. Location of the cathode-ray oscillograph near the divider for direct connection across the low-voltage capacitor also is undesirable, since this introduces stray capacitance and inductive effects on the cathode-ray beam.

In the capacitance-shielded and guarded-resistor type of divider, capacitance shielding has been accomplished in two ways:

1. Höhl[8] placed a capacitor and resistor divider in parallel and made the time constants of the two sections thus formed identical.

2. The Allmanna Svenska Elektriska Aktiebolaget (ASEA)[4] investigated the divider with a screen, sometimes termed a "doughnut" or a "pie-plate," on the upper end of the divider.

Either of these methods seem to eliminate the undesirable effects of the capacitance to ground. If one considers the response of such a compensated divider without the cable lead, however, it is found to be limited in accuracy by the inductance. The uncompensated surge-resistor divider may be nearly as satisfactory if careful attention is paid to the spacing of the equipment in the laboratory. The ASEA also added a nonlinear resistive element around the measuring resistor to equalize the nonlinearity of the capacitance voltage distribution. It would seem that such a resistance would tend to increase the inductance.

In all of these types of compensated dividers the cable lead is still a part of the circuit and cannot be properly terminated under all conditions, and hence must contribute to the over-all error.

Analysis of the Repeated-Structure Network

Since electrical impulse measurements are concerned with the recording or observing of transitory voltages or currents, a transient analysis of any network used to make such measurements is desirable. The method of the Laplace transformation offers a powerful and relatively simple means for such analysis and will be used throughout.[7]

Simplified Attenuating Network

In Figure 4(A) is shown a simple network in which the output voltage $e_o(t)$ can be made an attenuated replica of the input voltage $e_i(t)$ if the impedance of the cathode-ray oscillograph is neglected. This may be seen readily from the following analysis.

By definition

$$E_i(s)=\int_0^\infty e_i(t)\epsilon^{-st}dt \tag{1}$$

and

$$E_o(s)=\int_0^\infty e_o(t)\epsilon^{-st}dt \tag{2}$$

where $E_i(s)$ is the Laplace transformation of the input time signal $e_i(t)$; $E_o(s)$ is the Laplace transformation of the output response $e_o(t)$; and $s=\sigma+j\omega$ a complex variable.

For no initial energy storage in the network

$$E_o(s)=\frac{Z_2(s)}{Z_1(s)+Z_2(s)}E_i(s) \tag{3}$$

where the impedance functions are

Figure 2. An equivalent circuit of the surge resistor

Figure 3. Capacitor voltage divider

$$Z_1(s)=R_1\frac{L_1C_1s^2+\left(R_1C_1+\frac{L_1}{R_1}\right)s+1}{L_1C_1s^2+2R_1C_1s+1} \tag{4}$$

and

$$Z_2(s)=R_2\frac{L_2C_2s^2+\left(R_2C_2+\frac{L_2}{R_2}\right)s+1}{L_2C_2s^2+2R_2C_2s+1} \tag{5}$$

Now if

$$R_1C_1=\frac{L_1}{R_1} \tag{6}$$

and

$$R_2C_2=\frac{L_2}{R_2} \tag{7}$$

then

$$Z_1(s)=R_1 \tag{8}$$
$$Z_2(s)=R_2 \tag{9}$$

Hence

$$E_o(s)=\frac{R_2}{R_1+R_2}E_i(s) \tag{10}$$

Since $e_o(t)$ is the inverse Laplace transformation of $E_o(s)$, equation 10, it is apparent that

$$e_o(t)=\frac{R_2}{R_1+R_2}e_i(t) \tag{11}$$

Equation 11 shows that $e_o(t)$ is exactly of the same form as $e_i(t)$ but of reduced amplitude.

If s is set equal to $j\omega$ in equation 10 where ω is interpreted as angular frequency, there may be written

$$\frac{E_o(j\omega)}{E_i(j\omega)}=\frac{R_2}{R_1+R_2} \tag{12}$$

Equation 12 represents the relative amplitude and phase of output to input when the input is a sinusoidal voltage.

This ratio is a constant independent of frequency.

Any attempt to observe or measure the output voltage $e_o(t)$ by means, for example, of a cathode-ray oscillograph alters the terminating impedance $Z_2(s)$ as expressed by equation 9 and the condition expressed by equation 11 no longer holds. Some deviation of the output observed from that of the input may be expected.

For simplification, assume the input to the cathode-ray tube to be represented by a pure capacitance C_o. Combining C_o with the impedance $Z_2(s)$ to form $Z_2'(s)$, the input and output then are related by

$$E_o(s)=\frac{Z_2'(s)}{Z_1(s)+Z_2'(s)}E_i(s) \tag{13}$$

where

$$Z_2'(s)=\frac{R_2}{R_2C_os+1} \tag{14}$$

On substituting equations 8 and 14 in equation 13 there is obtained

$$E_o(s)=\frac{R_2}{R_1+R_2}\frac{1}{\dfrac{R_2}{R_1+R_2}R_1C_os+1}E_i(s) \tag{15}$$

Some measure of the closeness with which $e_o(t)$ follows $e_i(t)$ may be determined by assuming $e_i(t)$ to be a step function of amplitude V. For such an input

$$e_o(t)=\frac{R_2}{R_1+R_2}V(1-e^{-t/T}) \tag{16}$$

where

$$T=\frac{R_2}{R_1+R_2}R_1C_o \tag{17}$$

The ratio $R_2/(R_1+R_2)$ must be chosen to give the desired voltage division, hence for the undesired transient term to be of minimum duration the product R_1C_o must be minimized. By minimizing the time constant T this divider may be satisfactory for the measurement of voltages which have no discontinuities as in a step function and which do not exceed a specified maximum rate of change with time.

To adapt this network to high-voltage impulse measurements it may be altered as shown in Figure 4(B). The terminating resistance R_2' must be the characteristic impedance of the cable (assuming the cable to be lossless). There are some reflections, however, since the cable is not lossless. To minimize reflections from the sending end of the cable R_2 also should approximate the cable characteristic impedance. This assumes that $R_1 \gg R_2$ so that a large voltage division is attained. This type of network may prove satisfactory where the accuracy requirements are not too stringent; but however, it does not appear that the inherent difficulties could be overcome for very short impulse measurements.

A Universal Voltage Division Network

A network constructed of simple-T sections is shown in Figure 5. The following analysis indicates that by proper choice of the components in each section an attenuating network results which has the property of passing any kind of signal without alteration of form. The Laplace transformation of voltage and current at the nth section is (see appendix)

$$E(s,n)=E(s,0)\cosh\beta(s)n-Z_o(s)\,I(s,0)\sinh\beta(s)n \tag{18}$$

$$I(s,n)=I(s,0)\cosh\beta(s)n-\frac{E(s,0)}{Z_o(s)}\sinh\beta(s)n \tag{19}$$

At the nth section output terminals, the termination, the voltage and current transforms are related by

$$E(s,N)=Z(s)I(s,N) \tag{20}$$

where $Z(s)$ is the terminating impedance function. By setting $n=N$ in equations 18 and 19 and substituting in equation 20 the input current to the network is found to be

$$I(s,0)=\frac{\cosh\beta(s)N+\dfrac{Z(s)}{Z_o(s)}\sinh\beta(s)N}{Z(s)\cosh\beta(s)N+Z_o(s)\sinh\beta(s)N}\times E(s,0) \tag{21}$$

Eliminating $I(s,0)$ between equations 18 and 21

$$E(s,n)=\frac{Z(s)\cosh(N-n)\beta(s)+Z_o(s)\sinh(N-n)\beta(s)}{Z(s)\cosh N\beta(s)+Z_o(s)\sinh N\beta(s)}\times E(s,0) \tag{22}$$

Writing equation 22, in equivalent exponential form

$$E(s,n)=\frac{e^{(N-n)\beta(s)}+\gamma(s)e^{-(N-n)\beta(s)}}{e^{N\beta(s)}+\gamma(s)e^{-N\beta(s)}}\times E(s,0) \tag{22A}$$

where

$$\gamma(s)=\frac{Z(s)-Z_o(s)}{Z(s)+Z_o(s)} \tag{23}$$

the reflection ratio function.

If the terminating impedance is identical to the characteristic impedance, the reflection ratio function is zero. In this event equation 22A becomes

$$E(s,n)=e^{-n\beta(s)}E(s,0) \tag{24}$$

Under the same condition for which the characteristic impedance is realizable at the termination, the function $e^{-n\beta(s)}$ is independent of s. Equation 67 of the appendix then becomes

$$e^{-n\beta(s)}=(\nu-\sqrt{\nu^2-1})^n=\left(\frac{1}{k}\right)^n \tag{67}$$

where k is a constant and may be defined as the attenuation per section. The function ν (equation 59 of the appendix) becomes independent of s if the impedance ratio functions α, μ, and λ are made independent of s. The complete voltage transform solution then is

Figure 4. (A) Simplified attenuating network (B) Schematic arrangement for remote location of the cathode-ray oscilloscope

Figure 5. Repeated-structure network composed of T sections

$$E(s,n)=\left(\frac{1}{k}\right)^n E(s,0) \tag{25}$$

which has the inverse Laplace transformation

$$e(t,n)=\left(\frac{1}{k}\right)^n e(t,0) \tag{26}$$

This simple relation shows that the voltage at the output terminals of any section is identical in form to the input voltage $e(t,0)$. The voltage across the terminating characteristic impedance is

$$e(t,N)=\left(\frac{1}{k}\right)^N e(t,0) \tag{27}$$

which is the voltage desired to be observed or recorded.

If the repeated-structure network is composed of simple-T sections, as shown in Figure 5, the characteristic impedance is

$$Z_o(s)=Z_2(s)\sqrt{\lambda^2(s)-1} \tag{28}$$

where

$$\lambda(s)=\nu(s)=\frac{Z_1(s)+Z_2(s)}{Z_2(s)} \tag{29}$$

If the impedance ratio function $\lambda(s)$ is made frequency independent, the characteristic impedance becomes physically realizable at the termination. By equation 29 it is apparent that if $Z_1(s)$ and $Z_2(s)$ are made of similar components then $\lambda(s)$ can be made frequency independent. In Table I are shown a few examples where λ is but a numerical constant. If the vertical plates of a cathode-ray tube are connected directly across the terminating impedance and the network is of the type A, C, or D shown in Table I, the capacitance of the plates may be considered as part of the required termination, thus permitting the ideal condition of including the recording instrument as part of the characteristic impedance termination.

A simple and convenient means for precision adjustment of the section parameters exists. Setting $s=j\omega$ in equation 25 gives

$$\frac{E(j\omega,n)}{E(j\omega,0)}=\left(\frac{1}{k}\right)^n \tag{30}$$

This expression shows the network to be capable of passing sinusoidal signals without phase shift, and that the amplitude ratio of output to input voltage is a constant for all frequencies.

Impulse Generator with Repeated-Structure Voltage Divider

In Figure 6(A) is shown a schematic arrangement for generating a transient voltage of prescribed form. With the repeated-structure network properly terminated the divider may be represented by the characteristic impedance $Z_o(s)$. With the capacitor C_v charged to a voltage v and the switch thrown to the right, the Laplace transformed voltage $E(s,0)$ may be obtained from the mesh equation

$$\left[\frac{1}{C_v s}+Z_g(s)+Z_p(s)\right]I_g(s)-Z_p(s)I(s,0)=\frac{v}{s} \tag{31}$$

$$Z_o(s)I(s,0)=E(s,0) \tag{32}$$

$$Z_p(s)[I_g(s)-I(s,0)]=E(s,0) \tag{33}$$

From these relations

$$E(s,0)=\frac{Z_p(s)}{\left[Z_g(s)+Z_p(s)+\frac{1}{C_v s}\right]}\times\left[1+\frac{Z_p(s)}{Z_o(s)}\right]-\frac{Z_p(s)}{Z_o(s)}Z_p(s)\ \frac{v}{s} \tag{34}$$

Since $e(t,0)$ is the inverse Laplace transformation of $E(s,0)$, equation 34, and

$$e(t,N)=\left(\frac{1}{k}\right)^n e(t,0) \tag{27}$$

it follows that the desired testing wave form may be obtained by adjusting the impedances $Z_g(s)$ and $Z_p(s)$, and the observed voltage $e(t,N)$ will be exactly of the same form. Note that the characteristic impedance of the voltage divider will influence the shape of the testing wave. The relative effect of $Z_o(s)$ may be controlled to almost any desired amount by proper choice of the impedances $Z_p(s)$ and $Z_o(s)$.

To illustrate, assume that a network of type A, Table I, was chosen for both $Z_p(s)$ and $Z_o(s)$ as shown in Figure 6(B). Then the impedance ratio

$$\frac{Z_p(s)}{Z_o(s)}=\frac{R_p\,R_oC_os+1}{R_o\,R_pC_ps+1} \tag{35}$$

If $R_oC_o=R_pC_p$

$$\frac{Z_p(s)}{Z_o(s)}=\frac{R_p}{R_o} \tag{36}$$

Table II. Various Sections Derived from the Parallel-T

TYPE SECTION	CHARACTERISTIC IMPEDANCE	IMPEDANCE RATIO FUNCTION
PARALLEL T 	$Z_0(s) = \frac{\mu^2-1}{1+a\frac{\mu^2-1}{\lambda^2-1}}\frac{Z_3(s)}{\sqrt{\lambda^2-1}}$	$\nu = \frac{\mu+a\lambda\frac{\mu^2-1}{\lambda^2-1}}{1+a\frac{\mu^2-1}{\lambda^2-1}}$
BRIDGED T  $Z_4(s) = 2Z_3(s)$	$Z_0(s) = Z_3(s)\sqrt{\frac{\lambda^2-1}{1+2\frac{Z_1(s)}{Z_3(s)}}}$	$\nu = \frac{\lambda^2+\frac{Z_1(s)}{Z_3(s)}\lambda-1}{\lambda^2+\frac{Z_1(s)}{Z_3(s)}-1}$
SINGLE T 	$Z_0(s) = Z_2(s)\sqrt{\lambda^2-1}$	$\nu = \lambda$
PI  $Z_4(s) = 2Z_3(s)$	$Z_0(s) = \frac{Z_2(s)}{\sqrt{\lambda^2-1}}$	$\nu = \frac{Z_1(s)+Z_2(s)}{Z_1(s)}$

By making R_s very much greater than R_p their ratio, equation 36, becomes negligible and the divider has small effect on the wave form. Thus

$$E(s,0) = \frac{Z_p(s)}{\frac{1}{C_ps}+Z_0(s)+Z_p(s)}\frac{v}{s} \tag{37}$$

For the impedance shown in Figure 6(B)

$$E(s,0) = \frac{1}{s^2+\frac{R_pC_s+R_pC_0+R_sC_p}{R_sC_pR_pC_s}s+\frac{1}{R_sC_pR_pC_s}} \times \frac{v}{R_pC_p} \tag{38}$$

This expression may be written

$$E(s,0) = \frac{1}{\left(s+\frac{1}{T_1}\right)\left(s+\frac{1}{T_2}\right)}\frac{v}{R_pC_p} \tag{39}$$

where the two time constants may be adjusted so that $T_1 \gg T_2$. The inverse Laplace transformation of $E(s,0)$, equation 39, is of the form

$$e(t,0) = K(e^{-t/T_1} - e^{-t/T_2}) \tag{40}$$

as shown in the sketch of Figure 6(B).

It is apparent from equations 34 and 27 that the repeated-structure network may be used not only for measurement but for wave shaping as well. While in the above illustration the influence of the voltage divider was negligible, this need not always be the case. For example, the impedance $Z_p(s)$ may be omitted entirely, and the voltage divider itself be so designed to give the desired wave form.

Experimental Measurements

Prototype Divider

The cathode-ray oscillograph when used with some suitable voltage-divider

Figure 7 (above). Test circuit for measuring the voltage divider frequency response

Figure 8 (right). Frequency response of one section, network A, Table I

(1) $R=R_o$ $C=C_o$ (2) $R=R_o$ $C<<C_o$ (3) $R=R_o$ $C>>C_o$

has been generally accepted as the instrument best adapted for the measurement of surge voltages. The input impedance to the vertical plates of a cathode-ray tube may be represented by a parallel combination of resistance and capacitance, similar in form to the characteristic impedance of network A, Table I. The equivalent parallel resistance, caused by convection currents between the plates, is sufficiently large to be neglected in most instances.

A prototype divider consisting of three T-sections, network A, Table I, was constructed. The T-section was chosen for experimental study because of its simplicity. Each branch of the T was composed of a special carbon-type resistor of 10,000 ohms ±1 per cent, in parallel with a capacitor of 90 micromicrofarads, ±0.5 micromicrofarad. The resistive element in the termination was adjusted to a value of 17,350 ohms (R_o, Table I). The capacitive element in the termination consisted of the vertical plates of a cathode-ray tube and the input capacitance to a vacuum-tube voltmeter. In addition a variable air capacitor was connected in parallel with the above combination, and by means of an impedance bridge the total capacitance was adjusted to 52 micromicrofarads (C_o, Table I).

This prototype divider was tested as suggested by equation 30. The essential elements of the test circuit are shown in Figure 7. The output and input voltages, $E(j\omega, N)$ and $E(j\omega, 0)$ respectively, were measured by means of two vacuum-tube voltmeters over the frequency range zero to 5 megacycles. The ratio of input to output voltage as a function of frequency was thus obtained. Measurements were made on each of the three sections separately, then on two sections in cascade, and finally on all three sections in cascade. A plot of amplitude ratio as a function of frequency for a typical set of tests on a single section is shown in Figure 8. Curve 1 was obtained with the shunt resistor of the termination having resistance equal to that of R_o, and the shunt capacitance equal to C_o, the values which according to equation 30 give a constant ratio of input to output voltage, and zero phase displacement between these voltages. It will be noted that the ratio remains constant over the entire frequency range. The results of measurements on two and three sections in cascade were similar to those obtained with one. The ratio $E(j\omega,0)/E(j\omega,N)$ remained constant within ±2 per cent from 0 to 5 megacycles, the ratios then being 13.93 and 52 respectively.

The effect of detuning the terminating impedance also is shown in Figure 8. When too little capacitance was present, the voltage ratio decreased at high frequencies as shown by curve 2; and when too much capacitance was present, the voltage ratio increased at high frequencies as shown by curve 3. Detuning the terminating capacitor by 10 micromicrofarads had no significant effect on the voltage ratio over the frequency range zero to 5 megacycles; however, a slight phase shift became noticeable at 5 megacycles, as shown in the oscillogram Figure 10(A). Oscillograms were taken at the same time the measurement of the voltage ratio was made on the divider.

The input voltage $E(j\omega,0)$ was applied to the horizontal plates and the output voltage $E(j\omega,N)$ was applied to the vertical plates of a cathode-ray tube. The resulting pattern was a Lissajous figure which was a straight line when both voltages were in time phase. Oscillograms were taken for one, two, and three sections, but oscillograms are shown for one section only, since with more than one section the ratio was so great that only a small vertical deflection could be obtained.

Photographs of Lissajous figures were taken at frequencies of 200 kc, 1 megacycle, and 5 megacycles per second and are shown in Figures 9(A), (B), and (C) respectively. No evidence of phase shift is observable. Figures 9(D), (E), and (F) are photographs of Lissajous figures taken with the same test circuit and at the same frequencies but with the type A voltage divider replaced by a surge-resistor divider of the conventional type. For this conventional divider considerable phase shift above 1 megacycle is present. In addition, the attenuation increased by a significant amount.

Figures 10(A), (B), and (C) show the effect of improper termination of a single section of the type A divider. Reference has already been made to (A) in which the terminating impedance was detuned by a change of 10 micromicrofarads in the capacitance. In Figure 10(B), at 1 megacycle no terminating capacitance is present excepting that of the vertical plates of the cathode-ray tube, and in Figure 10(C) also taken at 1 megacycle, the termination is 200 micromicrofarads rather than the critical value of 52 micromicrofarads. The phase shifts in (A), (B), and (C) show the importance of proper termination of the network.

A resistor divider of type B, Table I, also was constructed and tested. The resistors in each branch of the T were the 10,000-ohm resistors which have already

been described. Measured voltage ratio as a function of frequency is shown in Figure 11(A). This result is similar to that shown by curve 3, Figure 8, where the terminating capacitance was too large. The small capacitance of the cathode-ray tube, vacuum-tube voltmeter, and leads come into effect at the higher frequencies. It may be concluded that in a divider network consisting only of resistor arms, correct termination is impossible when the measuring equipment has capacitive impedance. A Lissajous figure for 1 megacycle is shown in Figure 10(D). The resulting large phase shift is obvious.

A divider of type *C*, Table I, also was constructed using 90-micromicrofarad capacitors and terminated by a total capacitance equal to C_e. Figure 11(B) shows the amplitude ratio of a typical test made in one section. Deviation of the voltage ratio from the ideal value at the lower frequencies is caused by convection currents between the plates of the cathode-ray tube. It is thus evident that in a divider network consisting of capacitance arms only, correct termination is impossible when the impedance of the measuring equipment has a resistive component.

A 3-section divider of type *D*, Table I, also was constructed and tested. The resistors and capacitors were the same as those already described. Inductors of approximately 500 microhenrys were placed in series with the resistors. As in the preceding cases the divider was terminated in its characteristic impedance and tested. The constancy of the voltage ratio with frequency for one section is shown in Figure 11(C). The appearance of the Lissajous figure, Figure 10(E), is typical of the condition in which there is no phase shift. The results for the other sections individually and for two and three sections in cascade were equally good. This indicates that although considerable inductance is present in the arms of a divider network, by correct design and termination a good voltage divider may be realized.

Finally a network of type *E*, Table I, was constructed and tested. The results show that this type of network would not be satisfactory, as may have been expected from the foregoing discussion. The characteristic impedance could not be realized with the cathode-ray tube connected across the termination. For the same reason this eliminates the possibility of realizing a good voltage divider of type *F*, Table I, if the value of R_1 is at all appreciable.

The type *A* divider, Table I, was next tested for transient response. The output terminals of the wave-shaping circuit shown in Figure 12 were connected to the input terminals of the divider. The capacitor C_e was charged from a d-c source and then discharged through thyratrons V_b and V_e and the associated circuit. The wave shape was controlled by the resistors R_e and R_b. The sweep in each case was carefully calibrated by a timing wave and could be measured accurately to about 0.2 microsecond. Figures 13(A) and (B) show oscillograms taken of input voltage $e(t,0)$ and output voltage $e(t,N)$ for correct termination. Figures 13(C) and (D) show oscillograms taken of the output voltage for incorrect termination. When the network is incorrectly terminated, the output wave shape is far from being a reproduction of the input wave. Photographic enlargements of Figures 13(A) and (B) were made and the input wave was plotted in Figure 14.

Points obtained from the output wave were multiplied by the theoretical attenuation factor and also are shown on the same figure. The fact that the points computed from the output wave lie almost directly on the input wave shows the high degree of accuracy in wave reproduction which may be obtained with a correctly designed and terminated voltage-divider network.

In Figure 15 are shown oscillograms of the input and the output transient voltages for one section of the type *D* network with the correct value of terminating impedance. Note that each output response is a replica of the input wave, the

network itself introducing no apparent distortion.

In Figure 16 is shown a schematic arrangement for switching an impulse repeatedly onto the voltage divider input terminals.[8] By repeating the transient in this way it was possible to obtain photographs of both input voltage $e(t,0)$ and output voltage $e(t,N)$ for a relatively fast sweep. The input circuit was closed in consecutive intervals by allowing mercury drops falling under the influence of gravity to act as a switch when bridging two contacts. The cathode-ray oscillograph sweep, exponential in form, was initiated by the mercury switch. The time axis of the cathode-ray oscillograph was calculated from the known values of resistance and capacitance in the cathode-ray oscillograph sweep circuit. A cable, T_4, introduced sufficient time delay to allow the sweep to begin before the impulse arrived at the divider input terminals. Figure 17 shows input and output voltages where the divider consisted of one section of network D, Table I. No deviation of output from input is observable.

Large Scale Model

A larger model capable of measuring up to 50,000 volts peak was constructed.

Figure 14. Graphical plot from photographic enlargements of Figures 13(A) and (B)

This supposedly was a network of the type A, Table I, consisting of a single section in which the impedances $Z_1(s)$ and $Z_2(s)$, Figure 5, were made identical. The resistive elements consisted of the 1,000 ohm noninductive resistors which had been used for the surge-resistor divider described earlier in the paper. The inductance of each 500-ohm card was less than 3 microhenrys.

Suspension insulators were used for the capacitor units. The capacitance of each of a number of insulators was measured by an impedance bridge and those selected for the divider had a capacitance of 39 micromicrofarads, ±0.5 micromicrofarad.

A frequency response test was made, as was done with the prototype dividers, and the results were unsatisfactory. It was found that the length of leads was extremely critical. It was found possible, however, to obtain satisfactory results if the lengths of the leads in each section element were made identical. The foregoing essentially noninductive resistors were then replaced by some wire-wound ceramic coated resistors. These resistors had an over-all length of about 15 inches and a resistance of 20,000 ohms plus appreciable inductance. With these resistive-inductive elements the results were excellent. The voltage ratio was constant with frequency, and no phase shift was detectable.

The reason for the improvement is the fact that the inductance of the leads was appreciable and the divider was thus of the type D rather than of the type A. The inductance of the leads was more or less indeterminate so that it was difficult to obtain the correct values of L_1 and L_2 for the type D divider of Table I. However, the inductance of the ceramic-coated resistor units was large compared with the inductances of the leads and since the inductances of the units were essentially equal, the type D divider was readily produced. This, we believe, emphasizes one advantage of the network-type divider, that is, the stray inductances of the leads need not in any manner vitiate the ideal characteristics of the divider.

In order to obtain greater attenuation in the large-scale model the shunt impedance $Z_2(s)$ which consisted of suspension insulator units in series was replaced by an oil-filled capacitor of 5,850 micromicrofarads, and this capacitor was shunted by a resistor of 133 ohms. This change gave an attenuation of 300 for the single section. In addition, the elements of the terminating impedance were adjusted to conform to the new value of shunt impedance. With this high value of attenuation it was not possible to compare input and output voltages. However, an oscillogram of the output response was taken for a surge rising slowly to 27,200 volts and applied to a chopping gap, Figure 18(A). A surge generator of the conventional type was used. The 27,200 volt peak recorded on the oscillogram, Figure 18(A) was within 2 per cent of the mean breakdown voltage for the sphere spacings of the chopping gap.

Figure 15. Oscillograms for network D, Table I, one section with correct termination

(A) Input voltage
(B) Output voltage for input (A)
(C) Input voltage
(D) Output voltage for input (C)

The surge-generator circuit was then adjusted to produce a $1^1/_2$ by 40-microsecond wave, the maximum value of which was 29,000 volts. The oscillogram of the output wave is shown in Figure 18(B). The sweep was not fast enough to delineate the wave front too clearly, but so far as the oscillogram can be analyzed, the output response corresponded with the $1^1/_4$-microsecond wave front.

In order to test this large-scale model more completely, both a cold-cathode type of oscillograph and a glass-tube type each with a very fast sweep that can be synchronized with the surge generator are needed. With instruments of this type the model can be tested with impulse of very short duration, and the input and output can be accurately computed.

This work is being undertaken at the present time.

Conclusions

1. Present-day methods of surge testing as well as a review of the literature shows that there is a need for increasing the accuracy of the present methods of measuring impulses of very short duration.

2. The repeated-structure network described in the paper has been shown by rigorous analysis to possess the ideal characteristic of an attenuating network for passing any kind of signal whatsoever without distortion. Experimental results from tests made on the simple T-structure are sufficiently favorable to indicate that a practical improved high-voltage divider of high accuracy may be constructed. When a cathode-ray oscilloscope is used as the measuring instrument and its input impedance becomes a part of the terminating impedance, networks of type *A*, *D*, and possibly *C* are particularly suitable.

3. The effect of the impedances of the connecting leads was not explicitly accounted for in the analysis, but it is apparent that any possible effects can be disregarded if the impedances of the leads be included in the required impedances of the arms of the network and if all connection lead impedances are made negligible with respect to the branch impedances.

4. The effect of stray capacitance to ground can either be compensated for or made negligible by proper choice of the circuit parameters in the networks of type *A*, *C*, or *D* in Table I.

5. In the past, improvement in dividers for high-voltage measurements has been accomplished by such means as: reduction of inductance by using bifilar wound resistors; minimizing stray capacitance by isolation of the divider; and reduction of the input capacitance to the cathode-ray tube by using a specially designed tube. In the repeated-structure network type of voltage divider, however, the presence of inductance as part of the resistive elements may be desirable; stray capacitance may be either compensated for or neglected; and the input capacitance to the cathode-ray tube may be incorporated as part of the terminating impedance.

6. The need for a cable lead to the measuring instrument is eliminated since the divider itself can be made of sufficient length so that the measuring instrument and similar equipment may be located at a remote distance from surge generator.

Figure 18. Oscillograms for large-scale model, network D, Table I

(A) Output voltage with chopping gap
(B) Output voltage approximately $1^1/_2 \times 40$ wave

7. The practicability of the network type of voltage divider for very high voltage, 1,000,000 volts and higher, has so far been given only general consideration by the authors. The theory is completely presented and only the practical design remains. While suspension insulators may be used for the capacitive system, the authors feel that capacitor units having much greater values of capacitance and which are less affected by humidity would be preferable. Since the requirements for the capacitive system are only moderate, the cost should not be excessive. Because of less exacting requirements the resistor units can be made at less cost than the present ones. Moreover, the divider may be so designed that the largest part of the voltage drop occurs in the first section making the voltage rating of subsequent sections only moderate. We realize that the elimination of stray capacitance and inductive effects may present some problems for the first section, at least.

Appendix. Derivation of the Laplace Transform Solution of the Repeated-Structure Network

Consider a repeated-structure network consisting of parallel-T sections having impedances as shown in Figure 19. For no initial energy storage within the network, the Maxwell mesh equations are

$$[Z_1+Z_3]I_a-Z_3I_b=E(s,n) \tag{41}$$
$$-Z_3I_a+[Z_1+Z_3]I_b=E(s,n+1) \tag{42}$$
$$[Z_3+Z_4]I_c-Z_4I_d=E(s,n) \tag{43}$$
$$-Z_4I_c+[Z_3+Z_4]I_d=-E(s,n+1) \tag{44}$$

where

$$I_a+I_c=I(s,n) \tag{45}$$
$$I_b+I_d=I(s,n+1) \tag{46}$$

All quantities are Laplace transformed, the (s) notation for brevity being dropped from the branch impedances and mesh currents. Eliminating all but the input and output currents of the section there results

$$Z_{\omega\mu}I(s,n)-Z_4I(s,n+1)=\left[1+\alpha\frac{\lambda\mu-1}{\lambda^2-1}\right]\times E(s,n)+\alpha\left[\mu-\frac{\lambda(\lambda\mu-1)}{\lambda^2-1}\right]E(s,n+1) \quad (47)$$

$$-Z_4I(s,n)+Z_{\omega\mu}I(s,n+1)=\alpha\frac{\mu-\lambda}{\lambda^2-1}E(s,n)-\left[1+\alpha+\alpha\frac{\lambda(\mu-\lambda)}{\lambda^2-1}\right]E(s,n+1) \quad (48)$$

where

$$\alpha=\frac{Z_4}{Z_2} \quad (49)$$

$$\lambda=\frac{Z_1+Z_2}{Z_2} \quad (50)$$

$$\mu=\frac{Z_3+Z_4}{Z_4} \quad (51)$$

Equations 47 and 48 are algebraic equations in s and difference equations in n. Interpolating the points of $E(s, n)$ and $I(s, n)$, section voltage and current transforms respectively, by a jump function[7]

$$Z_{\omega\mu}\int I(s,n)-Z_4\int I(s,n+1)=\left[1+\alpha\frac{\lambda\mu-1}{\lambda^2-1}\right]\int E(s,n)+\alpha\left[\mu-\frac{\lambda(\lambda\mu-1)}{\lambda^2-1}\right]\int E(s,n+1) \quad (52)$$

$$-Z_4\int I(s,n)+Z_{\omega\mu}\int I(s,n+1)=\alpha\frac{\mu-\lambda}{\lambda^2-1}\int E(s,n)-\left[1+\alpha+\alpha\frac{\lambda(\mu-\lambda)}{\lambda^2-1}\right]\times\int E(s,n+1) \quad (53)$$

By definition

$$\mathcal{L}\left[\int E(s,n)\right]=\mathcal{E}(s,w)$$

$$\mathcal{L}\left[\int I(s,n)\right]=\mathcal{I}(s,w) \quad (54)$$

The Laplace transformation of equations 52 and 53 with respect to n is

$$Z_{\omega\mu}\mathcal{I}(s,w)-Z_4e^{w}[\mathcal{I}(s,w)-I(s,0)P(w)]=\left[1+\alpha\frac{\lambda\mu-1}{\lambda^2-1}\right]\mathcal{E}(s,w)+\alpha\left[\mu-\lambda\frac{\lambda\mu-1}{\lambda^2-1}\right]\times e^{w}[\mathcal{E}(s,w)-E(s,0)P(w)] \quad (55)$$

$$-Z_4\mathcal{I}(s,w)+Z_{\omega\mu}e^{w}[\mathcal{I}(s,w)-I(s,0)P(w)]=\alpha\frac{\mu-\lambda}{\lambda^2-1}\mathcal{E}(s,w)-\left[1+\alpha+\alpha\lambda\frac{\mu-\lambda}{\lambda^2-1}\right]\times e^{w}[\mathcal{E}(s,w)-E(s,0)P(w)] \quad (56)$$

Solving equations 55 and 56 for $\mathcal{E}(s,w)$ and $\mathcal{I}(s,w)$ respectively

$$\mathcal{E}(s,w)=\frac{[e^{w}-\nu]E(s,0)-\dfrac{Z_4[\mu^2-1]}{1+\alpha\dfrac{\mu^2-1}{\lambda^2-1}}I(s,0)}{e^{2w}-2\nu e^{w}+1}\times e^{w}P(w) \quad (57)$$

$$\mathcal{I}(s,w)=\frac{[e^{w}-\nu]I(s,0)-\dfrac{1+\alpha\dfrac{\mu^2-1}{\lambda^2-1}}{Z_4[\mu^2-1]}[\nu^2-1]E(s,0)}{e^{2w}-2\nu e^{w}+1}\times e^{w}P(w) \quad (58)$$

where

$$\nu=\frac{\mu+\alpha\lambda\dfrac{\mu^2-1}{\lambda^2-1}}{1+\alpha\dfrac{\mu^2-1}{\lambda^2-1}} \quad (59)$$

Now if e^{w} is regarded as the variable instead of w, the characteristic equation of the network is

$$e^{2w}-2\nu e^{w}+1=0 \quad (60)$$

from which

$$e^{w_1}=\nu+\sqrt{\nu^2-1}$$

$$e^{w_2}=\nu-\sqrt{\nu^2-1} \quad (61)$$

and

$$e^{w_2}=e^{-w_1}$$

Expanding equations 57 and 58 in partial fractions, as described in reference 7, Chapter IX, the inverse Laplace transformation with respect to w is

$$E(s,n)=E(s,0)\frac{e^{w_1n}+e^{-w_1n}}{2}-Zo(s)I(s,0)\frac{e^{w_1n}-e^{-w_1n}}{2} \quad (62)$$

$$I(s,n)=I(s,0)\frac{e^{w_1n}+e^{-w_1n}}{2}-\frac{E(s,0)}{Z_o(s)}\frac{e^{w_1n}-e^{-w_1n}}{2} \quad (63)$$

where

$$Z_o(s)=\frac{Z_4[\mu^2-1]}{1+\alpha\dfrac{\mu^2-1}{\lambda^2-1}\sqrt{\nu^2-1}} \quad (64)$$

Replacing w_1 by a more suitable term $\beta(s)$, the propagation function, the solution may be written

$$E(s,n)=E(s,0)\cosh\beta(s)n-Z_o(s)I(s,0)\sinh\beta(s)n \quad (65)$$

$$I(s,n)=I(s,0)\cosh\beta(s)n-\frac{E(s,0)}{Z_o(s)}\sinh\beta(s)n \quad (66)$$

From equation 61 it may be seen that $e^{w_2n}=e^{-w_1n}$, and

$$e^{-n\beta(s)}=\left[\nu-\sqrt{\nu^2-1}\right]^n \quad (67)$$

The bridged T-section is obtained from the parallel T-section upon setting $Z_4=\infty$ (or $Z_1=\infty$); the simple T is obtained upon setting $Z_3=\infty$ (or $Z_1=\infty$); and the pi section is obtained upon setting $Z_3=0$ and $Z_4=\infty$ (or $Z_4=0$ and $Z_3=\infty$). This fact is illustrated in Table II.

If the impedance ratio functions α, μ, and λ are made independent of frequency, the realization of the characteristic impedance at the termination of the above described repeated-structure networks is possible. This is demonstrated in Table I for the simple T.

Discussion

P. A. Abetti (General Electric Company, Pittsfield, Mass.): The authors are to be commended for a thorough and accurate analysis of the voltage transfer characteristics of repeated-structure networks. The solution of the difference equations which arise from such types of networks is greatly facilitated by the Laplace transformation of jump functions, as was done by the authors. The electrical engineer therefore finds a familiar tool employed on rather unfamiliar equations, usually treated separately in the "difference calculus", which is not generally taught in engineering schools.

I think that a more general approach to the problem investigated by the authors might clarify the physics of the phenomena. Briefly, it is desired to investigate, analytically and experimentally, various types of networks for surge-voltage measurement. These networks should, ideally, reproduce faithfully the impulse voltage shapes in reduced scale, without any form of distortion.

Network theory gives assurance of this characteristic of the network under investigation, for all impulse voltages, of any shape, by either one of the two equivalent tests:

1. At all frequencies, from zero to infinity, the amplitude ratio of output to input voltage must be constant, and the phase shift must be zero. This is equation 30 of the paper. Actually, since amplitude and phase characteristics are interdependent, only one of these requirements is sufficient in theory.
2. A unit impulse function must be transmitted undistorted by the network.

It is easily seen that these two requirements are equivalent, by observing that the Fourier spectrum of the unit impulse function $U(t)$ contains all frequencies, all with the same amplitude. This is shown by the complex form of its Fourier integral

$$U(t)=\Re e\left[\frac{1}{\pi}\int_0^\infty e^{jwt}dw\right]$$

The authors, instead, used for their transient tests applied waves as that of Figure 13(A). Assuming for simplicity, that this wave may

Figure 1. Amplitude spectrum of 0x15 microseconds wave

be represented as a decaying exponential

$$V(t)=\epsilon^{-\alpha t}$$

of tail length 0.693 $1/\alpha$, its Fourier integral expression is given by

$$V(t)=\mathcal{R}e\left[\frac{1}{\pi}\int_0^\infty \frac{e^{j\omega t}}{\alpha+j\omega}d\omega\right]=\frac{1}{\pi}\int_0^\infty \frac{\omega \sin \omega t+\alpha \cos \omega t}{\alpha^2+\omega^2}d\omega$$

The amplitude spectrum of the impulse wave is

$$S(\omega)=(\omega^2+\alpha^2)^{-1/2}$$

an expression which is a function of α, and therefore of the wave-tail. For a tail length of 15 microseconds, which corresponds to the wave of Figure 13(A), the amplitude spectrum is plotted, according to this equation, in Figure 1 of the discussion. It is seen that only the lower frequencies are present, and that their amplitude is not constant.

Thus the fact alone that this particular wave was reproduced satisfactorily by the divider does not guarantee that all other impulse waves will be reproduced in the same manner.

Although the unit impulse function may not be obtained in practice, it may be approximated in a satisfactory manner by the modern "pulse testing" techniques[1,2,3] which have found useful application in the fields of communication and electronic engineering.

As explained before, the steady-state measurements for all frequencies and the "pulse tests" are equivalent. It is therefore expected that the latter will take the place of the former for the determination of the characteristics of those networks which are used principally in the investigations of transients.

Finally, I think that papers by A. M. Angelini[3] and by S. A. Nazarov[4] could be added to the references given in the paper.

A. T. Thompson (Harvard University, Cambridge, Mass.): The potential dividers, introduced by the authors in this most interesting paper, have been tested to 5 megacycles. That this frequency testing range is quite adequate is briefly discussed here.

Consider the general surge of Figure 2 of the discussion. This is a $a\times10^6\times\frac{1}{2}(a+b)\times10^6$ wave, since it reaches its peak value E in $a\times10^6$ microseconds, and takes $\frac{1}{2}(a+b)\times10^6$ microseconds to reach $\frac{1}{2}E$ on the wave tail. The expression for this surge is

$$\epsilon=f(t)=\begin{cases}0, & -\infty<t<0\\ \frac{E}{a}t, & 0<t<a\\ \frac{E}{a-b}(t-b), & a<t<b\\ 0, & b<t<\infty\end{cases} \qquad (a<b) \qquad (1)$$

By use of the Fourier transform,

$$F(\omega)=\int_{-\infty}^{\infty} f(t)\epsilon^{-j\omega t}dt \qquad (2)$$

we obtain the frequency spectrum of this surge

$$F(\omega)=\frac{E}{a\omega^2}\left(\frac{b}{b-a}\epsilon^{-j\omega a}-\frac{a}{b-a}\epsilon^{j-b\omega}-1\right) \qquad (3)$$

From equation 3 of this discussion, the amplitude spectrum can be obtained by plotting the absolute value of $F(\omega)$ as a function of ω. This is shown for the severe case of a 1/4×5 wave in Figure 3 of the discussion. The dashed lines are used to connect calculated points since a smooth connecting curve would violate the variations due to the term $1/38\epsilon^{-j\omega b}$, whose effect, for our purposes, is negligible. The frequencies of appreciable amplitude are seen to be clustered about the origin. The relative amplitudes of the high-frequency components are negligible. This fact is generally true for surge voltages because the amplitude spectrum is inversely proportional to ω^2, as shown by equation 3 of the discussion. For this reason, then, it is concluded that a frequency testing range of 5 megacycles is adequate.

J. H. Park (National Bureau of Standards, Washington, D. C.): This paper contains a very thorough and desirable treatment on the use of the Laplace transform in obtaining solutions for repeated-structure networks. It also clearly indicates how such a treatment can be used in obtaining a theoretical analysis for certain special types of voltage divider networks. However, as in practically all theoretical treatments of a voltage divider for measuring high-voltage surges, the conditions imposed by the theory are difficult if not impossible of attainment in the laboratory. The type of T-section most nearly attainable in the laboratory conforms to D shown in Table I. The restriction, $L_1/R_1=L_2/R_2$, is possible of fulfillment if sufficient care is exercised. However, since C_1 must include stray capacitance from all parts of the high-voltage sections of the "T" to ground the restriction, $R_1C_1=R_2C_2$, is not attainable unless a high-voltage capacitor is actually inserted at C_1 with sufficient capacity to swamp out stray capacitance. Since, in any full-scale high-voltage surge testing equipment the physical size of at least some of the T-sections must

Figure 2 (below). A general surge voltage

Figure 3 (right). Amplitude spectrum of 1/4x5 surge

be large, stray capacitance to surrounding grounded objects is quite large and somewhat variable depending on the location of the adjacent grounded objects. Thus, to eliminate the effects of stray capacitance, several capacitors capable of withstanding nearly the full peak surge output voltage of the generator would be needed. Even after obtaining such capacitors the troubles are not entirely eliminated because such capacitors are of necessity large physically and even in the best designs contain inductive residuals, the inductive effect predominating at frequencies above 2 megacycles, in most cases. It is the general conclusion of this writer that theoretical treatments are most helpful but can only be used as a guide in predicting the qualitative performance of high-voltage surge dividers.

An experimental approach is needed for evaluating the quantitative performance characteristics of any high-voltage divider. The writers of the present paper have made a good start in this direction but in the end results should be based on measurements made on a full scale high-voltage divider because it is readily seen that the effect of stray capacitance increases vary rapidly with increase in size of the circuit elements. It also is the opinion of this writer that steady-state measurements to be meaningful should include a range of frequency extending at least as high as 15 megacycles with suitable equipment. This is necessary because of the high-frequency superposed oscillations always present in a high-voltage surge generator.

The authors of this paper conclude that the main advantages of using a repeated-structure network as a voltage divider are that it would eliminate the use of a cable to the cathode-ray oscillograph and would permit exact matching of the cathode-ray oscillograph deflecting plate circuit. These deductions are based on theory using lumped circuit constants, whereas any actual circuit is composed of both lumped and distributed constants. Where the length of the circuit begins to be comparable or greater than the wave length of the highest frequency component of the voltage being measured, the adequacy of lumped circuit theory must be checked experimentally.

The authors of this paper are to be congratulated on their presentation of a thorough analysis of a difficult problem, and have presented interesting experimental results.

J. H. Hagenguth (General Electric Company, Pittsfield, Mass.): The subject of the paper is very timely. There is a need for a simple voltage divider to measure steep-front impulse waves. As pointed out in the paper, there have been numerous methods proposed to compensate dividers for use in accurate voltage measurements for times of the order of 1 microsecond and less. The drawback of all methods is that no standards are available to check the accuracy of the response of the divider, particularly at the high ratios required for measurements beyond a few hundred thousand volts.

The calculations presented in the paper suggest that T-networks have an excellent high-frequency response and that even very steep wave fronts can be transmitted faithfully. However, experimental proof is given for only single sections or relatively low divider ratios. It is hoped that such measurements are practical for higher ratios.

As pointed out in the paper, accurate reproduction of all branch constants is needed to eliminate distortion. Network D, Table I, appears to have given the best experimental results. For high voltages of the order of 500,000 volts or more, the first capacitance elements to ground may have relatively high inductances in series, and these will have to be matched throughout the structure.

A voltage divider for practical laboratory impulse work should have the following characteristics:

1. Accurate reproduction of wave shape between 0.1 microsecond and several hundred microseconds.
2. Occupy small space.
3. Not be influenced by external fields.
4. Ratio must be readily adjustable in small steps.
5. Influence the wave shape as little as possible.
6. Possible to connect directly across the test specimen.

These are the principal requirements. If methods can be developed to check divider ratio and phase shift for the higher ratios required, the divider described in the paper should be very useful to the industry.

C. L. Dawes, C. H. Thomas, and **A. B. Drought:** It is gratifying to the authors to learn that those who have discussed the paper substantiate its theoretical basis, and up to the limits of our experimentation give general approval of the results which so far have been obtained. Many of the limitations, and suggestions which have been made for further experimental study were realized early by the authors; and research in these directions has been conducted for some time.

Mr. P. A. Abetti shows by the Fourier integral that the unit impulse function $U(t)$ contains all frequencies, all of which have the same amplitude. This is known as the Dirac impulse function and goes to infinity and returns to zero, all in zero time while enclosing a unit area, a condition which is not realizable in practice. In practice, the impulse is finite in both magnitude and duration, and may be assumed to have a rectangular wave shape. This type of impulse also contains all frequencies, some of zero amplitude, but their relative magnitudes diminish rapidly as their order increases.

Mr. Abetti shows that, with a wave represented by a simple decaying exponential function, the relative magnitudes of the component waves diminish rapidly as the frequency increases. For this wave the relative amplitude at 5 megacycles is negligible, hence the testing frequency range from zero to 5 megacycles used by the authors appears to be quite adequate for this type of wave. Dr. J. E. Park states that the testing frequency should be carried to at least 15 megacycles. For mathematical impulses of 0.1 microsecond duration or less undoubtedly the frequency range of the sinusoidal tests should be extended. For an impulse of 1-microsecond duration, however, the relative amplitudes of frequencies above 5 megacycles are negligible.

Although, so far, we have been unable to obtain copies of references 3 and 4, we shall be only too glad to add them to our list, as the titles indicate that these papers must have direct reference to the work described by the authors. We appreciate the constructive contributions of Mr. Abetti, which will be of considerable assistance to us in our further investigations.

Mr. A. T. Thompson is continuing the investigation here at Harvard; and in his discussion gives the results of analyzing a 1/4 by 5 microsecond wave represented by two straight lines, using a method of analysis similar to that used by Mr. Abetti. This curve shows that for this particular wave, all frequencies above 1.5 megacycles are entirely negligible.

Dr. Park points out that the paper clearly shows the method of obtaining a divider that will reproduce faithfully the input voltage, but states that the theoretical conditions are difficult, if not impossible of attainment in the laboratory. We can appreciate the difficulties which he describes, and realize that the stray capacitances and other stray parameters inherent in a high-voltage divider, which necessarily occupies a large space, are not easily determined. However, the first step in the production of an ideal high-voltage divider is to determine the values of the parameters which it must have. This sets the goal toward which practical design can be directed. The paper at least does this. We agree with Dr. Park that the type-D section most nearly conforms to the requirements of a practical divider and this type of section is most readily attainable. The stray capacitances certainly cannot be exactly determined; but at least they can be approximated. It would not be necessary to make C_3 so large as to "swamp" out the entire stray capacitances, but rather to insert a known capacitor of sufficiently large capacitance to make negligible the errors incurred in determining the values of the stray capacitances. This, we feel, should produce an accuracy which is much greater than is attainable with the present-type divider in which the stray capacitances and the other stray parameters are entirely uncontrolled. The principal method now used is to attempt to eliminate them, and unsuccessfully, we believe. The paper describes how readily a 50-kv divider was produced with ordinary resistors, and capacitors consisting only of suspension-insulator strings. The resistors which had the higher values of associated inductance produced the greater accuracy because this inductance was "controlled" and is inherent in the type-D section. At the present time, we are constructing a divider for a voltage much higher than 50 kv and do not anticipate any insurmountable difficulty.

In the matter of eliminating the use of a cable to the cathode-ray oscillograph, Dr. Park states that the theory is based on using lumped circuit constants, whereas any actual circuit is composed of both lumped and distributed constants. In Figure 4 of this discussion we show a possible 500,000-volt voltage divider, consisting of only five sections and having a ratio per section of 13.8 to 1. The first two sections reduce the voltage from 500,000 volts to only 2,620 volts. The voltages associated with the last three sections are so low that no difficulty should be encountered in making them of lumped constants whose magnitudes can

Figure 4. (A) High-voltage divider, attenuation 13.8 per section (B) Circuit elements of each section (C) Termination, Z_0

be large compared with any distributed constants which will be encountered. These could form the oscillograph lead. As a matter of fact, at low voltage the units are small in size and the stray parameters also will be small and thus can be made definite, and by measurement the elements of each T-section can be adjusted to correct value.

Mr. Hagenguth states that in the paper, experimental proof is given only for single sections of the divider. This is true of the figures. However, with reference to Figure 8, it is stated in the paper that tests were conducted with two and three sections also, and results similar to those of Figure 8 were obtained. The same is true for the results shown in Figures 10 and 11. He also correctly points out that the ratio must be readily adjustable in small steps. The divider shown in Figure 4 of this discussion shows that a ratio of 13.8 to 1 per section can be readily obtained. With a divider made up of nine T-sections, the first two of which operate above 20,000 volts, a section ratio of 5-to-1 is easily attainable, thus giving a voltage ratio change by a factor of five per step. However, it is not at all difficult to provide a gradual change of voltage ratio at any of the low-voltage sections, such as dividing the 190 volts at the termination of the third section in Figure 4. Work now is being conducted on this phase of the divider, and it is hoped that it will be published in the near future.

In his last statement Mr. Hagenguth points out one great experimental difficulty, that of being able to check directly the ratio and phase angle. Obviously, in order to do this there must be a primary measuring device responsive to the input voltage, which may be as high as 500,000 volts or higher. So far as we know, at this time there is no such measuring device available. Obviously no voltage-reduction apparatus can be used, for it is the errors in such apparatus that are being studied. As more equipment becomes available we hope to be able to provide a type of direct-measuring apparatus which may respond perhaps to 100,000 volts at least. This same experimental difficulty occurs, even with low-voltage measurements. As sections are added and the ratio increases, the measuring apparatus, such as cathode-ray oscillographs, must be able to respond with the input and the output voltages directly applied to their deflection plates. No voltage reduction device and no amplifier can be used. Hence, the voltage ranges of the cathode-ray oscillographs which were available to us limited our experiments to three sections. The extension of the ratio by which direct measurement of the input and output voltages can be made is a problem on which we now are conducting research; and we are certain to extend the range far beyond our present limits.

We are appreciative of the interest taken by those who have discussed the paper and also of the analyses and suggestions which have been made.

The Irradiation of Spark Gaps for Voltage Measurement

D. R. HARDY
NONMEMBER AIEE

J. D. CRAGGS
NONMEMBER AIEE

THE American, British, and German standards relating to the measurement of high voltages by means of sphere gaps recommend that in certain circumstances, in order to ensure consistency of measurement, the gaps should be suitably irradiated. The amount of irradiation required is not specified in definite terms. However, it is known[1,2] that while insufficient irradiation may cause the gap to behave in an erratic manner as the result of excessive time lags, too much irradiation will introduce a space charge in the gap with a consequent lowering of sparking voltage. It is desirable, therefore, to know the optimum amount of irradiation for any given spark gap.

The effect of irradiation is to cause a prebreakdown current to flow in the gap. Experiments designed to determine this current have been carried out and are described in the paper. Ultraviolet and gamma irradiation have been used as these methods are recommended in the various standards, and appear to be the most suitable for such purposes.

From a knowledge of prebreakdown currents the number of electrons liberated per microsecond in the gap can be estimated and hence an indication given of the probable statistical time lag of the gap when subjected to impulse voltages.

Information is given of a new but obvious method of irradiation of spark gaps, that is, the use of a radioactive cobalt (Co60) which from preliminary tests would appear to be particularly suitable for this purpose.

It is recognized by several leading authorities (the American, British, and German standards), that irradiation in some form is necessary for certain gap dimensions but there is little agreement as to the nature and method of application of this irradiation. The value of the prebreakdown current set up in the gap as a result has been estimated by many workers in this field, but no attempt seems to have been made to correlate the value of this current with the form of irradiation used and the breakdown voltage obtaining.

Section 4-67 of the American Standards for Measurement of Test Voltage in Dielectric Tests[3] recommends irradiation by ultraviolet light and discusses in some detail the type of lamp to be used and its position relative to the gap. Little mention is made of the material and surface condition of the electrode apart from the fact that it should be kept clean. Several workers[4,5,6] in this field have measured the breakdown voltage for various gaps irradiated in this manner and have expressed their results as a function of intensity of illumination at the electrode surface. As shown in this paper, this is of little value since a variation of photocurrent (for the same light intensity) of as much as 200 times has been obtained under normal laboratory conditions. A very much smaller variation is claimed to produce appreciable errors in the value of breakdown voltage, particularly with impulse voltages, and it is in this respect that the present work is considered to be of value to other workers in this field.

The British Standard Rules for the Measurement of Voltage with Sphere Gaps[7] revised in 1939, recommends irradiation by "radioactive or other ionizing media" while the German Standard suggests ultraviolet light irradiation and polished copper spheres as electrodes.

Such diverse opinions would suggest that further information is required regarding the relative merits of these methods of irradiation and that some optimum value be recommended. The present work was designed to give information on the magnitude of the prebreakdown current for various conditions in the gap and it is hoped that further investigations now in progress will provide sufficient information to enable suggestions for the modification of the various standards to be made.

The Effect of Irradiation on Discharge Gap Breakdown

The formation of a spark discharge in a uniform electric field between parallel plate electrodes at the minimum breakdown voltage is preceded by an electron avalanche which crosses the gap from cathode to anode. The electron avalanche may be itself initiated by a single electron. Consequently, for the development of a spark in a discharge gap, at least one electron capable of initiating an avalanche must appear in the gap and preferably in the region of the cathode. The breakdown of a discharge gap is, of course, also dependent on the value of the applied voltage. If, say, an impulse voltage of a 2-microsecond duration is applied to the gap, the possibility of breakdown is remote unless free electrons occur frequently, that is, at the rate of at least 5×10^8 electrons per second, which corresponds to a current of 8×10^{-14} amperes.

Such a supply of free electrons may be provided if the gap is irradiated by any of the following agents:

1. Ultraviolet light, which is known to produce an appreciable amount of photocurrent from the surface of the electrodes.

Paper 50-90, recommended by the AIEE Instruments and Measurements Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted July 18, 1949; made available for printing December 5, 1949.

D. R. Hardy and J. D. Craggs are both with the University of Liverpool, Liverpool, England.

The experimental work described in this paper was carried out by D. R. Hardy and used as the basis for a thesis submitted to the University of London in fulfillment of the requirements for a Master of Science Degree.

The authors wish to express their appreciation of the assistance given and facilities provided by Professor Meek of the Electronics Department and Professor Teago of the Electrotechnics Department of the University of Liverpool.

2. A radioactive material, whose radiations ionize the gas between the electrodes and possibly also cause the emission of electrons from the electrodes.

3. A nearby corona or spark discharge which produces ultraviolet radiations and so ionizes the test gap and causes photoemission from the electrodes.

Corona has been used for the irradiation of spark gaps in lightning arresters. Sparks have been found to be a very effective source of irradiation and Street and Beams[8] showed that in certain conditions the voltage to sparkover, if maintained for 1 microsecond, could be reduced some 16 times when the gap was irradiated by a nearby spark.

The scope of this present paper is limited to the effects produced by ultraviolet light irradiation and radioactive materials since these methods are specifically mentioned in the American, British, and German Standards, and, furthermore, because they appear to be the more convenient from the point of view of quantitative measurement, which is desirable if standardization is to be obtained.

A summary of previous work on the breakdown of discharge gaps is given by Meek.[14] Since the publication of this latter paper Cooper[15] has shown that at high frequencies (2,800–9,800 megacycles per second) and for short duration recurrent voltage impulses a source of 0.2 milligram (mg) radium is sufficient to improve the performance of certain spark gaps. Cooper, Garfitt, and Meek[17] working with direct current and at power frequencies, have employed 0.2 and 0.5 mg of radium to irradiate 2-centimeter diameter spheres, and their final calibrations vary by up to $4^1/_2$ per cent, from the value declared in the British Standard.[7]

Experimental Methods

The measurements may be conveniently arranged in two main classes: those in which the spark gap is irradiated by ultraviolet light from a quartz mercury vapour lamp,[18] and those in which a radioactive source is used.

For each class of measurement a high voltage power supply was connected across a spark gap having parallel plate or spherical electrodes and the current flowing in the gap measured by means of an electrometer triode.[19] For the amounts of radium used, the plateau (or saturation) value of gap current for gap lengths of 1 centimeter occurred at about 100 volts. This value was subsequently chosen as the arbitrary level at which the two classes of measurement were to be compared.

When radium was in use it was usually enclosed in the anode but some tests were made with the source enclosed in the cathode. The activity of a radioactive cobalt cathode also was investigated.

Irradiation by Ultraviolet Light

The photoelectric current from an electrode surface is dependent upon several factors, the most important of which are the nature of the irradiating source, the electrode material, and the state of the electrode surface. Previous workers in this field have chosen to ignore some of these factors and, as will be seen, this is not permissible.

It is well known that the photocurrent from an irradiated surface decreases with time producing what is known as the "fatigue effect,"[20,21] but little consideration appears to have been given to the effect of this fatigue on the prebreakdown current in the discharge gap—which itself effects the minimum breakdown voltage.

The materials chosen for these tests were brass, copper, steel, and aluminum because they are frequently used in elec-

trode construction, and zinc, tin, and magnesium because they are known to produce an appreciable photocurrent when irradiated with ultraviolet light. All measurements were made with the irradiated electrode mounted in a guard ring.

Photoelectric Fatigue

After the various electrodes had been removed from the lathe they were immediately polished with a very fine grain emery paper (Durex 0/48 grade) and inserted in the discharge gap. The electrodes then were irradiated for several hours and measurements of photocurrents made at intervals. The results of this initial test are given in Figure 1(A). The electrodes were subsequently repolished in the same way and the curves of Figure 1(B) obtained.

It would appear from the two figures that for the same electrodes having nominally the same surface treatment there exists an appreciable variation in the rates of decrease of photocurrent. This matter was further investigated and several tests were made with each electrode material. Typical results are shown in Figure 2. The photoelectric fatigue does not appear to be a simple exponential phenomenon and is not consistent from test to test.

The Effect of Gap Voltage

The saturation or plateau value of current defines the state of ionization existing in a discharge gap before breakdown takes place, so that it is this value which is of importance when considering the effects of irradiation.

Tests were carried out on the various electrodes and the gap current measured for increasing voltages up to 10 kv. Typical curves are shown in Figure 3.

It is considered impossible to compare the "plateau" currents accurately for the various electrodes since their values obviously depend on the state of the electrode surface at the time the measurement is made and it has already been seen that the same repeated physical treatment of the surface of an electrode does not produce the same photocurrent output. It should be emphasized that, for the practical engineering uses to which sphere gaps are submitted, refined methods of treating the surfaces are not practicable.

The Effect of Light Intensity

It has been shown by many workers[20,21] that the photoemission from an electrode surface is proportional to the intensity of the incident light, and this was confirmed with the present apparatus on the assumption (justified by the recent work of Engstrom[22] on the same type of photomultiplier) that the photomultiplier current was proportional to the amount of light falling on its cathode.

The Effect of Surface Condition

The state of the electrode surface is defined in the various standards as follows:

The American Standard gives no indication as to the state of the electrode surface beyond the fact that it should be kept clean.

The British Standard states that the electrode surface shall be clean and that a high degree of polish should be avoided, but does not indicate the manner in which the cleaning shall be carried out. The German Standard, however, recommends the use of polished copper spheres.

It is considered of interest, therefore, to investigate the effect of surface condition on the photocurrent output of the various electrodes.

The electrodes were each tested after polishing with emery paper, a polishing powder, and a liquid polish which contained an abrasive and mineral spirits. Typical results obtained are shown in Figure 4. The results obtained for the materials tested are in no way consistent and since, in any case, it is unlikely that the same surface condition could be reproduced exactly, the diagram indicates only the order of photocurrent to be expected.

Figure 5. Effect of period of inactivity on photoelectric current

Each material represented by block of three columns. First column. Fatigue in last test prior to inactivity period; Second column. Subsequent fatigue (without repolishing) after inactivity period of two weeks; Third column. Effect of immediate repolishing on fatigue rate. Steps in columns indicate photoelectric current after ultraviolet irradiation for 25 seconds, 10 minutes, and 5 hours respectively. Method of polishing-fine emery paper and powder in lathe at about 1,500 rpm

Block 1. Brass electrode; 2. Zinc electrode; 3. Magnesium electrode; 4. Copper electrode

The Effect of a Period of Inactivity

It is considered likely that in an engineering laboratory some appreciable time may elapse between measurements and it is, therefore, of interest to investigate the effect of such a period of inactivity upon the photocurrent output.

After polishing, the electrodes were each irradiated with ultraviolet light for a period of five hours and then allowed to stand in the laboratory for a period of two weeks. They were then rubbed lightly with cotton wool to remove grease and dust and retested without further repolishing. The electrodes were then again repolished and further tests carried out. The results obtained are shown in block diagram form in Figure 5. A large reduction of photocurrent (10 to 30 times for the particular tests carried out) may be effected if the electrode is initially

Figure 6. Effect of interrupted irradiation by ultraviolet light

(A). Copper electrode
(B). Zinc electrode

polished, irradiated, and then allowed to stand unirradiated for some time. If, as might be the case in practice, the electrodes were not used for voltage measurements until some minutes after polishing the reduction in photocurrent would be perhaps some four or five times for the above conditions.

The Effect of Interrupted Irradiation

To investigate the above effect further, tests were carried out on zinc and copper electrodes with interrupted irradiation. The results are shown in Figure 6. Both electrodes appear to recover their photoelectric properties and upon further irradiation tend to follow the original fatigue curve. The copper electrode, Figure 6(A), appears to fatigue less rapidly when the ultraviolet light source is cut off.

Irradiation with Radioactive Substances

It is well known that the ionization which occurs in the proximity of a radioactive substance may be due, in varying degrees depending on circumstances, to the emission of α, β, or γ rays. The α-particles (helium nuclei) ionize very heavily along their paths in a gas but are, therefore, so easily absorbed that they do not emerge from the usual radium capsules. With thin electrode coatings of, for example, polonium, the α-particles are able to produce strong ionization in a spark gap.[34,35] The β and γ rays (respectively fast electrons and very hard electromagnetic radiation) cause less ionization per centimeter path per particle, than do the α rays. The γ rays are by far the least efficient.

Most of the natural β rays from radium are stopped by about 1 millimeter of copper and so the use of radium capsules (usually with nickel or nickel-alloy envelopes) in general restricts the ionization effects in a spark gap to those caused by the γ rays. With these the direct air ionization is relatively unimportant compared with the ionization caused by the secondary electrons ejected from the electrodes by the γ rays.

Previous workers have made use of some or all of these effects as sources of irradiation. Berkey[33] obtained some favorable results using a radium solution (the content of which was not specified); Garfitt[34] employed a polonium-coated cathode; while Dillon[35] used a polonium alloy, but in each case the active life of the ionizing agent was comparatively short. Van Cauwenberghe[36] employed a radium capsule which ensured a stable performance and long life but the ionizing power was much reduced since the α-rays and the greater part of the β-rays would be absorbed by the capsule itself.

The authors have shown, however, that an activated cobalt[28,29] electrode is possessed of the required characteristics of a long stable life and appreciable activity.

Radium

The use of radium is generally accepted as most convenient for the usual type of laboratory measurement, and it was, therefore, selected for investigation.

Measurements were made with radium capsules containing 0.1, 0.2, 0.5, and 1 mg in the cathode and in the anode of various metal electrodes, polished and unpolished, but little difference was found in measured current for the electrodes used. At first, the cathode was arranged as the central electrode of a guard ring but it was realized that secondary electrons liberated from the earthed outer ring or in the space between the cathode and guard ring, would pass into the cathode, which was at a slightly higher potential (about 1 millivolt per 10^{-13} ampere), due to the current flowing through the electrometer grid resistance, and thereby cancel part of the true gap current. The order of magnitude of this effect can be seen from Figures 10 and 11(A). An apparent reduction in gap current of some 10 times occurs for the radioactive cobalt cathode and for the radium irradiated cathode.

The location of the radium in the

cathode (curve 2, Figure 11(A), where thickness of metal to radium is 0.068 centimeter) and in the anode (curve 3, Figure 11(A), where the thickness of metal to radium is 0.038 centimeter) shows little difference in the order of current measured. With a guard ring, however, the apparent current was found to reverse (that is, the effect of secondary emission was to swamp the real gap current) when the thickness of metal between the radium and the gap was increased to some 0.5 centimeter.

It was expected that the depth of the radium source in the electrode (that is, thickness of electrode between source and gap) would affect the gap current, and this is confirmed in Figure 7.

With 2-centimeter diameter spheres and 2-centimeter diameter flat plates as electrodes, the gap current at 100 volts and with gap length 0.01, 0.1, and 1.0 centimeters, was measured for metal thickness from about 0.03 to 0.3 centimeter, the irradiating source being 1 mg radium situated in the anode.

The currents measured for the two sets of electrodes is seen to be of the same order, about $2\text{–}3\times10^{-13}$ amperes per square centimeter of electrode projected area.

The results of Figure 7 expressed as a function of gap length are shown in Figure 8. Currents measured with 0.1, 0.2, and 0.5 milligram radium with 0.03 centimeter metal thickness for spheres and 0.038 centimeter for flat plates also are included in these figures.

From Figure 8 the value of gap current for the spherical and flat plate electrodes (for the same thickness of metal over the same radium source) is not greatly reduced for very small gap lengths. It seems unlikely that much of the ionization current is caused by secondary electrons ejected from the electrodes since most of it should be due to the "tertiary" ionization produced by the secondary-electrons in the gap. This is because the secondary electrons may have very high energies (100 to 1,000 kilo-electron volts) and are, therefore, capable of producing many "tertiary" ion pairs. The curves of Figure 8 were, however, taken at constant gap voltage so that for very small gap lengths the voltage gradient would be very high (10 kilovolts per centimeter at 0.01 centimeter) and, therefore, due to this change of voltage gradient, the effect of secondary emission could not be followed. In Figure 9 results were taken at a constant value of voltage gradient and these curves indicate that the ionization current is caused by the liberation of "tertiary" electrons in the air gap, for at small gap lengths the gap current approaches zero.

From the curves of Figure 8 it will be seen that 1 mg radium enclosed by a thin skin of metal in the anode produces a current of the order of 10^{-11} amperes for the electrode considered with a gap length of 1 centimeter and voltage 100 volts. This current is equivalent to approximately 1 electron per 0.016 microsecond. These electrons appear at random through out the gap but in a uniform field only an electron appearing near the cathode will initiate an electron avalanche leading to the formation of a spark when the gap is subjected to a voltage just sufficient to cause breakdown. If one assumes that say 10 per cent of the electrons are produced in the region close enough to the cathode to be effective in initiating the spark breakdown of the gap, then the number of such initiating electrons is one per 0.16 microsecond for the above conditions. Consistent behavior of the particular gap when subjected to impulse voltages of magnitude slightly in excess of the d-c breakdown value may, therefore, be expected when the duration of the impulse is about 1 microsecond for flat plate electrodes and perhaps 10 microseconds for spherical electrodes (since perhaps 10 per cent of the projected area of the spherical electrode is effective for sparking). Erratic behavior may, therefore, be expected for impulses of less than 0.1-microsecond and 1-microsecond respectively.

Radioactive Cobalt

Radioactive cobalt which now can be produced in fairly large quantities in uranium piles, can be used for the purpose of sphere gap irradiation with certain advantages over other methods. It is relatively cheap; electrodes can be machined from it and then irradiated in a pile so that the defects of thin polonium layers[24] are overcome; the half life is 5.3 years; the γ-ray energies are 1.3 and 1.1 mega-electron volts and the β rays (0.3 mega-electron-volts maximum) also should be of use in cases where the γ rays, which liberate more electrons from the electrodes than from the air or other gas in the interelectrode space of the gap, do not give sufficient ionization.

The current produced in the gap by the activated cobalt is shown in Figures 10 and 11. Here it is seen that an activity equivalent to about 10 mg of radium is obtained. This should prove to be extremely useful for the irradiation of small gaps where 0.2 mg radium has previously been found to be ineffective.

Conclusions

With ultraviolet light irradiation the necessary free electrons required to initiate the breakdown of a discharge gap are provided as photoelectrons emitted from the irradiated electrode (cathode) surface. It is unlikely that many electrons would be produced by photoionization in the gas or at dust particles, but the effect of the latter in some circumstances may be important. The effectiveness of ultraviolet light as an irradiating agent depends, therefore, on the state of the electrode surface and differs appreciably for different electrodes. The fatigue of the electrode surface which is found to occur to some degree for all the materials tested, and especially the inconsistency of this quantity, suggests that it is impossible to estimate with accuracy in ordinary laboratory conditions (which are not those of advanced vacuum physics) the

prebreakdown current existing in a particular discharge gap. Unless irradiation by ultraviolet light is to be supplied to such an extent that makes polishing unnecessary, it is considered that over a period of time the accuracy of voltage measurement will deteriorate appreciably. This requirement will probably necessitate a source of great intensity, especially at the higher voltages because of the greater distance required between lamp and electrodes, but too high an irradiation is to be avoided since it tends to lower the value of voltage required to spark-over. Meek[17] has calculated values for the lowering of breakdown voltage for various gap currents, and it appears that, for a zinc electrode where the gap current was observed to vary from 10^{-10} to 5×10^{-12} amperes per square centimeter, under certain circumstances, a lowering of breakdown voltage of up to 5 per cent may be expected.

Radioactive materials can form very stable sources of irradiation and produce an ionization which is largely independent of surface conditions and to a large extent of the gap voltage. Since the γ rays give their effect by first producing at the metal surfaces fast secondary electrons which then cause the major part of the ionization, it would be expected that some influence of the nature of the electrodes would be apparent. In the present experiments such effects appear to be too small to be observed. As the gap length is increased at a constant voltage, the gap current increases and appears to attain a maximum value which, in the case of radium, varies in magnitude with the amount of radium present.

In the radium source used the monel-metal capsule and the electrode thickness cuts off the α rays and probably most, if not all, of the β rays. As these are known to be more effective ionizing agents than the γ rays, it would appear that the radioactive cobalt has the more desirable characteristics for spark gap work. Because the ionization produced by the radium decreases with increasing distance, it is considered necessary to locate the radium source at the cathode rather than at the anode so that a maximum ionization in the cathode region is obtained with a minimum amount of radium. Where it is anticipated that a nonuniform field form will exist and breakdown of the gap may be initiated at or near the high voltage electrode irrespective of polarity, it may be more effective to locate the radium capsule in the high-voltage electrode.

The radioactive cobalt proved to be a very stable source of ionization and in view of its high activity should prove to be a most useful means of spark gap irradiation.

For these reasons it would appear that in general spark-gap work radioactive substances provide a more satisfactory means of irradiation than ultraviolet light.

Centralized Instrumentation and Controls for Steam Electric Power Stations

B. C. MALLORY
NONMEMBER AIEE

THE ultimate in centralization of instrumentation and controls for a steam electric power station might be considered as having only one operator for the whole station, with this operator sitting in a quiet air-conditioned office with one load indicator, and with one control to start, adjust load, and stop each main turbine generator. The boiler for each unit and all other equipment would operate automatically and the operator's only duties would be to operate the load controls in accordance with telephoned instructions from the system load dispatcher. However, this ultimate in simplification is neither economical nor feasible for present-day steam turbine generators, boilers, and auxiliary equipment.

Once started and put on the line, a turbine with its boiler and complete set of auxiliaries may be so equipped today that it can be operated automatically. But, present-day equipment and controls are not sufficiently troublefree even with the best of maintenance programs, and are not to be trusted to operate satisfactorily without adequate attention. Nor, so far as the writer knows, have automatic controls been devised to start either a turbine or a large high-pressure boiler from a cold condition without manual assistance and careful checking by operators.

There is a vast amount of thought and effort that should be applied to developing reliable controls for automatic starting of boilers and turbines, especially from an overnight stand-by condition. Managements are asking engineers to consider seriously some automatic time clock device, possibly with temperature and vibration sensitive adjustments to co-ordinate starting procedures properly, both from the viewpoint of uniformity of operations and ease of control.

According to Cybernetics as described recently by Norbert Wiener,[1] "automatic factories without human agents, are only so far ahead of us as is limited by our willingness to put such a degree of effort into their engineering as was spent, for example, in the development of the technique of radar in the second world war".

Separate control points for each turbine generator and each boiler have been common practice in the past, with a separate switchboard room. Now, with increasing costs of operating personnel, more emphasis is being given to aggregating main control points at centralized locations in order to require the use of the fewest possible men.

For medium or large modern boilers or turbines, each control point may require an instrument and control board as much as 30 feet long, and each panel becomes complex with literally hundreds of items of indicators, recorders, controls, and alarm lights. To assemble several of these boards at a central location requires considerable space.

There is a wide divergence of opinion among designing and operating engineers with regard to the amount of centralization of control that is practicable. The problem of the extent of advantageous centralization revolves about the number of manual controls that can be handled by one man in time of trouble. The cartoon, Figure 1, illustrates and emphasizes what happens when there is trouble.

One operator can supervise many controls while everything is functioning properly and units are neither being put on nor taken off the line, but in times of trouble the number and complexity of the controls that one operator can handle depend to a large extent on the panel layout and the ability of the man. The number can be increased safely to some extent by a logical arrangement and use of different types of control handles for different types of control, so that routine adjustments become simplified and, in emergencies, the operator acts from habit without having to think out each step of what he should do.

Too often the artistic appearance or the space needed in the back of the panels for instruments has governed the board layouts. There is a need for miniature mechanical instruments comparable to those on electrical boards or to those used for large airplanes. Furthermore, for ease and reliability of operation, the instruments and controls should be segregated to permit manipulating the vital controls from a central point, with those having minor manual adjustments for efficiency and the historical items located at some less strategic point.

The advantages of complete centralized control with the switchboard located in the control room include:

1. Reduction in number of operators which minimizes cost of operating personnel.

2. Presentation of all pertinent data to one operator to give a better understanding of the plant as an integrated co-ordinated unit.

3. Ability of the operator to take corrective action simultaneously for two or more operations, should conditions demand.

4. Avoidance of communication errors.

5. Improvement in quality of operation. The better operating conditions of the centralized control room attract a higher type personnel. This means more than better thermal efficiency as it should give better maintenance of load during upset conditions, quicker restoration after an interruption, and better judgment in preventing an interruption.

Paper 50-91, recommended by the AIEE Power Generation Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30-February 3, 1950. Manuscript submitted November 4, 1949; made available for printing December 22, 1949.

B. C. MALLORY is Chief Mechanical Engineer with the Stone and Webster Engineering Corporation, Boston, Mass.

Figure 1. Preliminary operation

6. More automatic controls may be required, which tend to free the operator from details and permit more supervision.

The disadvantages of complete centralized control with the switchboard located in the control room include:

1. Space required for control room in heart of station. Adds to initial construction cost by adding building space and may add it for the full height of the station.

2. Each additional instrument and control adds equipment to be maintained and each is a potential source of trouble because it may function incorrectly.

3. Complexity of many instruments, controls, alarms, and lights requires a considerable training period for operators, especially if the mechanical and electrical men have to substitute for one another. With two mechanical men and one electrical man in a control room, this substitution might easily be required.

4. Added cost, due to either duplication of controls, or longer runs of instrumentation and control leads and the space required for them.

5. Higher rate of pay for operators having greater responsibility.

Figure 2. Main operating floor plan—Plant A

Figure 3. Main operating floor plan—Plant B

Four stations designed since the war, each with two 40,000-kw or larger turbine generators illustrate differing amounts of centralization of control.

Plant A

Plant A given in Figure 2 shows the main operating floor plan of a new station which has two 850-pound-per-square-inch 900-degree-Fahrenheit 80,000-kw units and two coal-fired boilers. The two boiler panels have been combined so that the men operating the boilers have a common control point. The two turbine generators have been located with their steam ends together so that the turbine operators have control points close together. The electrical control room is separate, just outside the turbine room, and approximately centered on the expected ultimate station of four or five units.

Operations are limited to two floor levels with a few minor exceptions. The forced and induced draft fans and the precipitator controls are located on the operating floor grade for ease of operation. The 440-volt switchgear also is on the operating floor and shown cross-hatched in Figure 2. Boiler feed pumps and their controls are located on the ground floor with the condensate and booster pumps. Boiler feed pump controls are duplicated on the boiler boards.

The complexity of even this relatively minor centralized arrangement may be emphasized from the following data: These two boiler panels are each 19 feet long, or a total of 38 ft for the two, and each has 42 indicators, 18 recorders, six controllers and 25 sets of start-and-stop pistol grip control switches, usually with three lights per switch. There are over 300 items for the two boilers. Each turbine panel is 13 feet long and has seven indicators, ten recorders, eight sets of start-and-stop push buttons, usually with three lights per switch. Communication between the electrical control room and the boiler and turbine rooms is by telephone and telautograph.

One company preferred this arrangement and objected to combining the boiler and turbine gauge boards on the basis that boiler and turbine operators are not readily interchangeable, each having very different duties. In some localities, with the arrangement shown, a boiler operator with a helper to patrol the boiler operating floor, and a turbine operator with a helper are required so that combining the boiler and turbine boards, or placing them close together in a separate room would not decrease the number of operators.

Plant B

Plant B given in Figure 3 shows the main operating floor plan of a new station with two 850-pound-per-square-inch 900-degree-Fahrenheit 60,000-kw turbine generators and four oil- and gas-fired boilers. The station has recently been extended with two more 60,000-kw units. Here the electrical control room was placed in the aisle between the boilers and the turbines at turbine operating floor grade and is centrally located in the completed station. The boiler boards are grouped together as are the turbine boards. For the equipment in the picture there are 110 linear feet of mechanical gauge boards which have over 300 functions for indicating, recording, and con-

trolling, not including lights and alarms for condensate, boiler feed, boiler, and turbine controls.

Plant C

Plant C given in Figure 4 shows the main operating floor plan of a plant extension having two 1,300-pound-per-square-inch 950-degree-Fahrenheit 100,000-kw turbine generators and four oil- and gas-fired boilers. This extension has a complete centralized mechanical and electrical control room located at operating floor level so that it is at the crossroads between the boiler and turbine rooms. In addition, there are individual gauge boards at the various equipment items. The control room is 40 by 130 feet. Figure 5 shows a view through the centralized control room from the boiler operating aisle, with the boiler feed pumps seen through the far door. The man stands at the boiler master panel, shown in detail in Figure 6, and the enclosed telephone booth is shown on the right. There are 378 annunciator drops in this room. Some control rooms are soundproofed and air-conditioned, but this utility soundproofs only the glass enclosed telephone booth and prefers to have the operators noise conscious with respect to characteristic and abnormal noises around the plant.

Figure 9. Main operating floor plan—Plant D

A separate panel is located in this control room for each boiler and each turbine including each house generator. Figure 7 shows the individual boards for two of the four boilers. In addition, there are miscellaneous mechanical instruments and controls on another long panel. In all, there are about 100 linear feet of panel for basically mechanical, and about 76 linear feet for basically electrical controls.

Figure 8 shows part of the electrical boards. Note that there are several rows of panels.

Each control room operator is given considerable training in what should be done in emergencies. The men are expected to operate both basically electrical and mechanical controls and after they have become trained in handling the controls it is thought that seven men per shift can operate the entire station.

There now appears to be a trend towards the single boiler-single turbine installation, which would have considerably reduced the number of instruments and controls.

Plant D

There are many interesting arrangements being tried to obtain most of the advantages of centralized control and yet to hold initial costs to a minimum. Plant D given in Figure 9 shows such an arrangement which has a separate electrical control room. This is the operating floor plan of a plant addition consisting of two 850-pound-per-square-inch 900-degree-Fahrenheit 40,000-kw preferred standard turbine generators. The plant is oil- and gas-fired. The boiler and turbine panels have been located together for each unit and the main panels have been simplified by placing historical or efficiency instruments on other panels, and locating only the instruments and controls necessary for start-run-stop operation at the central point. For each unit this centralized boiler-turbine board is about 24 feet long. Many indicating gauges have been combined in multipointer-type dials like multipointer draft gauges that have decreased the length of the panels.

A bench-board type of panel was investigated for this application, but it was found to require more building space as it required a mezzanine below the board for initial installation of pipes and wires, and for maintenance of the instruments and controls.

When the first unit of Plant D starts initial operation, it is expected that only three men per shift will be added to operate the gas-fired boiler, the turbine generator, and their auxiliaries, one of whom will be immobilized at the central steam control board and the others will circulate throughout the station; and a few months later when the second unit goes into service, one more man per shift will be added, making a total of four. No additional operators will be required in the electrical control room. For starts and stops, a man probably will be called from the other section of the plant, or the station watch engineer will assist.

In conclusion, the writer believes that for the initial unit in a new station which has no local distribution, the electrical control room and the boiler and turbine gauge boards may be centrally located. However, as more units are added, it appears more convenient to have a separate electrical control room and then to have an immobilized centralized steam board operator for each main turbine-boiler unit with the required number of auxiliary mobile operators.

An operator or group of operators can care for one turbine-boiler unit and ordinarily do a good job in case of trouble, but if they have more than one to cover there is a chance that any complication of difficulties may develop into a serious outage.

Many of the advantages of a centralized control room may be gained, and some of the disadvantages eliminated, by having a centralized point for the control of each single boiler-single turbine located between the boiler and turbine at the main operating floor level with the switchboard in a separate room where the electrical controls for several such single boiler-single turbine units and those of the outgoing lines would be located. The writer favors this latter idea on the premise that a good operator should be able to control a single boiler-single turbine unit gauge board, but that anything more than that with present-day equipment and controls does not give adequate care in times of trouble. This one man must have assistance in starting the unit and when the unit is running for circulating through the plant. The control board operator should be in close contact with the other operators.

Smaller instruments and controls are needed for basically mechanical operations in order to consolidate the many items required and shorten the panel boards. This might be accomplished by placing the operating mechanism of flowmeter controllers near the equipment controlled and having air loading pressures or electric wires only brought to the centralized control point.

Discussion

Frank V. Smith (Sargent and Lundy, Chicago, Ill.): This paper gives an excellent review of the degree of application of the idea of centralized station control. The experiences outlined should be helpful to both operators and designers.

With the basic principle, there can be little disagreement. It would clearly be efficient from an operating point of view to centralize the entire control of the station at one point. The only operating objection would appear to be the possibility of a disaster at this central point, putting the station out of service to a greater degree than would occur with a decentralized system.

However, after the desirability of the principle is accepted, two fundamental problems arise.

First, the physical problem of finding a location which will be suitable for both the initial installation and the ultimate growth of the station.

Second, the problem of the degree to which controls and instrumentation should be carried back to the central point particularly in connection with the starting up procedure.

With regard to the first problem, the most reasonable location for centralized control is between the boiler room and turbine room on the main turbine room floor. This results in the shortest connections for both electrical and mechanical control lines and also gives ready access to the major equipment. We have found that for smaller stations up to 30,000-kw units, there is no particular difficulty in making space available in this area for the control of outgoing feeders, generators, turbines, and boilers. This can be done without increasing the size of the building, particularly if the use of a separate room is avoided. These panels can be located toward the temporary end of the building for the initial installation of perhaps two units. The extension for future units can be made in a reasonable way by adding panels so that those adjacent to each other make a logical sequence.

In a larger station, however, the added complications in the way of carrier current, load control, more complete instrumentation, and so forth, necessarily force a compromise and result in a separation of some of the functions. A separate air-conditioned room becomes desirable, and if all of the electrical and mechanical boards are

located together, a room of at least 30 or preferably 40 feet wide is necessary. This probably result in adding to the size of the building which will be a costly procedure since the entire height of the building is involved.

It is because of this fact that practically all stations have been forced to separate some of the elements and the following separations have been used:

1. Feeder, generator, turbine, and boiler controls for one unit or a pair of units have been placed in a separate room from the next unit or a pair of units.
2. Feeder controls have been moved to a separate location from the generator, turbine, and boiler controls.
3. Feeder and generator controls have been moved to a separate location from the turbine and boiler controls.
4. Relays for feeders and generators have been moved to a separate location from the feeder, generator, turbine, and boiler controls.

In this connection, we have found that most operators seem to feel that:

1. All electric feeder controls should be in one location so that the operator will be fully aware of what is happening on all outgoing lines.
2. All electric generator controls should be in one location so that the operator can be aware of load division between units, excitation problems, and so forth; in general, but not necessarily, this location should be the same as the feeders.
3. Boiler and turbine controls should be all together for the entire station or, if separated, should be in convenient groups of related units for stations built on the unit system.

These preferences indicate that unless it is possible to so design the centralized control that the electrical board can be essentially continuous for the ultimate development of the station, it is better to move the electrical control to a separate room and centralize only the turbines and boilers.

When a separate room is chosen for the electrical control, its cost is less than that required to widen the space between the boilers and turbines since it is located in a smaller building at the side or end of the station.

The second problem as to the degree to which controls should be brought back to the central point revolves around the extent to which manpower can be saved by additional expenditures. It is apparent that the simple process of grouping together electrical boiler and turbine controls at one point will reduce the number of operators from that required if all of these functions are in separate places, although a higher type of operator will be needed.

However, there is considerable difference of opinion as to the degree to which the number of operators around the plant can be reduced by bringing back controls for starting equipment. Studies made on two roughly similar situations showed that while the initial investment was increased appreciably by motorizing valves, installing position indicators and bringing back other electrical devices and alarms to the control room so as to avoid the necessity of operators having to be at equipment during starting or for frequent inspection, one operating company felt that this would permit a saving of sufficient operators around the plant to justify the additional expenditure, while another operating company felt that no appreciable reduction would occur.

It appears that while there is no question that complete instrumentation should be provided in the centralized control room, there is some difference of opinion as to whether any great expenditure should be made to carry back to this point sufficient controls for starting major items of equipment without operators at the equipment involved. We will all look forward to further operating experience in this field.

Design and Operation of Central Control Rooms

B. F. BORGEL
NONMEMBER AIEE

Synopsis: A description of the experiences leading to the adoption of the central control system in the Warren, Pa. plant of the Pennsylvania Electric Company, the design features incorporated in this room; the operating experiences with this type of control to date; the basic changes which have been indicated by actual operation; and the costs involved in this type of control.

THE central control room of the Warren, Pa. station of the Pennsylvania Electric Company is basically a balanced combination of control and supervisory rooms, and is a result of that company's extensive investigation into the field of centralized control, as well as an indication of a firm belief in the advantages and economics of this type of plant control.

This particular installation is serving as a proving ground for various changes which will be incorporated in future plant design, and will therefore be used to illustrate the engineering policy being followed by the Pennsylvania Electric Company in this and future plants, and to bring forth the experiences encountered in the operation of this room. Though the soundness of the design has been amply proved in operation, experience has indicated several desirable basic changes which will be incorporated in future installations.

Due to the peculiar operating problems encountered on this system, the need for faster communication between the various operators on duty in a station has long been recognized. This system, which is spread over a mountainous area 300 miles in extent, is subjected to severe disturbances from electrical storms, which frequently isolate a generating station from the system, causing the loss of all the load except that in the immediate area.

During these conditions, the plant facilities must be maintained in such a manner which will permit immediate load pickup when tie lines are reclosed, and aggravating this situation is the fact that several of the stations are located in metropolitan areas, and other sections in which are located customers such as oil refineries, rayon mills, electric furnaces, and so forth.

In order to take advantage of the low generating costs represented by the Company's mine-mouth plants, power is frequently transmitted as much as 200 miles into the metropolitan areas. During these periods, the area plant must be able to pick up load from minimum to maximum in the event of any tie line disturbance, and to accomplish this without any objectionable drop in voltage or frequency.

Attempts have been made in the past to effect faster internal plant communication by various means. The first attempt was the installation of telephone stations at key operating positions. This led to the use of common loud-speaker systems, arranged to provide coverage of all operating locations.

The third move in this direction, was the location on boiler control boards of the governor control of the turbine served by that boiler, thus turning over to the boiler operator the control of turbine load. These moves definitely speeded operation during emergencies, and indicated more efficient operation during normal periods, but underlined the necessity for one key operator to be constantly cognizant of the condition of all equipment in the plant that he might properly co-ordinate the actions of the other operators.

To meet this demand, the central control room system was investigated and adopted to the particular needs of this company, as illustrated in Figure 1. It was not felt that a control room in which control of all equipment in the plant was concentrated was feasible, since experience had indicated that sufficient operators must be used to permit satisfactory operation of the plant manually upon loss of one or more controls.

It was felt that it would be advantageous to concentrate in a central control room sufficient indicating and alarm systems which would furnish the operator a full picture of plant operation at all times, as well as full control of all equipment required during periods of emergency operation. With this end in mind, the room was designed to incorporate as shown in Figure 2, the necessary equipment for:

1. Operation of boilers, generators, and station auxiliary power supply.
2. Indicating and recording supervision of turbines, hydrogen systems, and feedwater systems.
3. Annunciator alarms on miscellaneous plant equipment such as water screens, service pumps, storage tank levels, air compressors, and so forth.

Experience had indicated the desirability of control boards arranged for maximum ease of operation, and particular attention was paid to this phase of the design, as shown in Figure 2. Operation is facilitated by grouping of associated equipment and locating the various groups in a functional sequence.

For example, the sequence of operation of each boiler panel is from left to right, starting with the induced draft equipment, followed by the forced-draft equipment, and the two sets of pulverizers. Vertical segregation of all equipment has

Paper 50-92, recommended by the AIEE Power Generation Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, January 30–February 3, 1950. Manuscript submitted October 31, 1949; made available for printing January 6, 1950.

B. F. Borgel is with the Pennsylvania Electric Company, Johnstown, Pa.

Figure 1. Cross section of Warren Plant showing location of central control room

been followed. Thus, the remote control station and position indicators for the induced draft inlet vane drive unit are directly below the induced draft fan motor control stations and ammeters. All start-stop stations are in a horizontal line at one level, and all remote control stations are in a horizontal line at another level on the panel board.

On the station power boards, the switch controls are arranged horizontally by voltages and vertically by sequence of operation, as pictured in Figure 3. Maximum usage has been made of all available types of handles for control stations. Thus pistol grip denotes circuit breaker control, oval is used on remote operating controls, round smooth on governor and field controls, round knurled on current and potential transfer switches.

The instruments and draft gauges which indicate the changes resulting from control operation are located vertically above the corresponding control stations on the panel boards. The primary objective throughout was to provide a layout that would help the operator to think and to follow the correct sequence of operation.

Figure 4 shows the arrangement and relative locations of one boiler control board, and the turbine, hydrogen, and generator panels. Figure 5 illustrates the arrangement and location of the station power bench board, one boiler control panel, and the master combustion control panel.

The Warren plant was placed in service on August 15, 1948, and operation since that time has amply justified the faith of the engineers in the advantages of a central control room. The plant was manned with experienced operators in the central control room, and new operators with no previous power plant experience in all other operating posts.

No misoperation by the new operators, who work directly under orders of the control operator has resulted to date. During the start-up period we had a total of 17 trip-outs of the machines at full load due to staged relay testing and accidental trip-outs.

In all cases, the machine was resynchronized and the plant returned to full load in less than five minutes elapsed time. The best record for this performance was 1 minute, 30 seconds, in which case the operator did not trip out any mills, but being able to see at a glance the condition of the plant, resynchronized the generator and put on load, allowing his safety valves to open and dump the excess steam for the required period.

This operating condition was duplicated in another plant of this system which is identical in design with Warren, lacking only the central control room, and a minimum of 11 minutes was required from trip-out of the generator to re-establishment of full load on the unit.

Since the Warren control room was the first effort by the Pennsylvania Electric Company toward the use of centralized control in generating plant operation it,

was recognized that actual operation would indicate desirable basic changes in design which could be incorporated in future planning. These changes are as follows:

1. Concentration on the board fronts of only those indicating instruments which are required for minute-to-minute operation.

The board fronts on a central control room are by far the most expensive surface per square foot in the station, and such valuable space should be utilized only for instruments and controls which are vital to station operation. Recorders, which primarily register trends and provide permanent records should be located on the backs of the control cubicles, or in a location adjacent to the control room which would be readily accessible to the operator for periodic checking.

A common monitoring system covering all points of temperature on the equipment will be used, permitting constant checking by the operator. Investigations now are being made regarding the use of small indicating instruments in parallel with recorders such as steam flow-air, flow, water level, and so forth, on the board fronts, as well as the development of smaller meters for pressures and drafts.

It is felt that unless the board fronts in a control room are kept to such a length as will permit normal coverage by one operator, the major benefit resulting from central control design will be lost. Application of these principles of design would shorten the Warren boards by 30 per cent.

It is not beyond the realms of possibility that the future control room will comprise a bank of airplane-type instruments and miniature controls, so arranged that a station will be monitored and operated from a control seat.

2. Relocation of the generator hydrogen indicating and signal panel to a location adjacent to the actual hydrogen equipment, to provide guidance for the operator in making adjustments to the hydrogen supply to the generator, and to eliminate the hazard of hydrogen leakage into the control room.

3. Use of pressure transmitting devices with the sender located at the boiler drum or other pressure point and multiple indicating units in the control room and at other required locations, to avoid the danger of a pressure blowout in the control room, with the attendant disruption of electrical control circuits.

4. Phase-angle control of tie line loading and frequency applied directly to combustion control as well as to the governor control of the turbine. This will be done by employing a 2-element master combustion control, the primary element receiving its impulse from the phase-angle control and changing combustion rate simultaneously with changes in turbine loading, and the secondary element working on header steam pressure and correcting this pressure at a predetermined rate.

5. The control room will be rearranged to permit greater visibility of the plant by the control room operator. Experience has indicated that it is inducive to better operation if the operator is able to see the equipment he is operating.

6. Further studies of the lighting problems in connection with control

Figure 3. Generator, exciter, and station auxiliary power control benchboard

Figure 5. Relative location and arrangement of station auxiliary power benchboard, boiler panel, and master combustion control panel

Figure 4. Relative location and arrangement of boiler, turbine, hydrogen, and generator panels

rooms. At Warren, the lighting intensity in the control room is high in comparison to the rest of the plant to decrease eyestrain on the part of the operators.

Reference to Figure 3 will show that this has led to a condition in which the Thermopane glass enclosing the room acts as a mirror and hampers outside vision.

The Warren control room has served a secondary purpose aside from the operating advantages described previously, in providing data permitting a judgment on the economic advisabilities of this type of design to be made. This plant consists of two 30,000-kw namepate rating generators operated on a continuous basis at 40,000 kw each.

The plant is operated with six operators per shift, and a total force, including supervisors, of 53 men. Accurate cost data of the control room versus conventional design has been compiled, and show the additional cost of the Warren design to be $60,000.00 or $1.00 per kilowatt of nameplate capacity.

The direct savings accruing from this expenditure is the elimination of two shift operators, evaluated at $35,000 per year total. No attempt has been made to date to evaluate the return represented by faster and more efficient operation of the plant when required, but this has been a sizable amount.

In conclusion, this company is convinced of the economic feasibility of the modified central control room, when it is engineered to meet a specific purpose in a definite plant, and that capital invested in such construction provides a high continuing rate of return on the investment.

Discussion

C. P. West (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The operation of this plant departs from commonly-used practices in that control of the loading and excitation of the generators is chiefly placed in the hands of boiler-room operators rather than directly under the control of the operator handling the primary switchgear. This arrangement is claimed to be better because of close co-ordination of boiler control and generator output during emergencies. Under normal conditions when switching operations and load changes are planned in advance, communication between operators by telephone is said to be adequate. In many new plants, all these functions and the required operators are in one large control room. It would appear that this arrangement, with the proper grouping of switches and instruments on control boards in one location with specific operators responsible for each functional unit, would give the best contact between them with no increase in personnel.

The author emphasizes the need for smaller instruments for indicating and recording electrical, steam, and combustion conditions. This is necessary to bring these devices as close together as possible to facilitate operation and reduce the number of people required. The possible future use of miniature instruments and control devices is predicted. There have been other plants planned where the tendency has been toward large indicating instruments, as apparently space consideration was not a controlling factor. It appears to me that standard control switches, electrical indicating instruments about 4 inches square, and boiler and combustion control instruments as near to this as possible gives the best arrangement. Such indicating devices can be plainly seen and yet are not too bulky. Smaller instruments may be less accurate and are harder to read. Small

Figure 1 (left). Front view of control board

Figure 2 (right). Isometric view of control board enclosure

switching devices often require interposing relays with consequent complication of circuits and the increased hazards of more contacts and operating parts. A move toward either extremely large or extremely small devices appears to have little to recommend it.

A. H. Burkhalter (Ebasco Services Incorporated, New York, N.Y.): Mr. Borgel is to be commended for his work of reducing the size of control room equipment and the contribution which that size reduction has made toward greater accessibility to the operator of indications and controls.

We marvel at the similarity of his suggestions in paragraphs 1 and 3 of his summary to the basic design which we have embodied in a compact control board which we are using regularly to control the boiler, turbine, and generator of our new unit type stations of sizes up to and including 60,000-kw preferred standard turbine generators.

Figure 1 of this discussion shows this control board. It is only eight feet in length and has a front bench section. It is of tunnel-type construction with all electrical recorders, watthour meters, and relays for the boiler turbine generator unit mounted on the rear panel. All of the large recorders which, in the past, have required piping of such primary quantities as steam, water, and fuel gas, have been replaced by remote electrical retransmitting devices. The only space then required on the board for indication of these quantities is that required for the electrical receiving indicators from these retransmitting devices. The high-pressure gauges on the control board are replaced by 0–15 pounds-per-square-inch gauges operating by pneumatic retransmission from the primary elements located at the most convenient point on the boiler or turbine. These 0–15 pounds-per-square-inch gauges are of the small type mentioned in Mr. Borgel's paper. They, and the above electrical receiving instruments, are also part of a retransmitting system as suggested in the paper.

The drafts and pressures at various points in the air stream through the furnace are all read on airplane-type pressure gauges as suggested in the paper.

Annunciation is provided on the front panel of the board for the boiler, the turbine, and the generator by use of a 32-point luminous-window type annunciator for each.

The control switches used are standard rotary type mounted with minimum spacing wherever necessary. Supervisory control was avoided in order to maintain maximum simplicity and reliability.

The significance of any indication or control facility is indicated by its position in the mimic representation of the boiler, the turbine, or the generator. This mimic representation is carried on to include all primary piping or bus work associated with these primary divisions of the unit.

Figure 2 of the discussion shows an isometric view of an earlier model of the control board. This shows more clearly the bench and tunnel-type construction. It also illustrates the compactness of the board.

As mentioned earlier, this board has on it all the indications and controls necessary for operation of a 1,350-pounds-per-square-inch boiler with its fuel control and condensate handling equipment, a turbine with its condensing equipment, and a 60,000-kw preferred standard generator with its electrical auxiliaries. This is in sharp contrast to the several massive gauge boards and control boards which have heretofore been a part of any centralized control arrangement. This compact control board makes it possible for one operator to control more than one unit by concentrating all the controls which he needs into such a small area. This eliminates any question of vertical versus horizontal centralization, since it accomplishes both.

The first two of these boards were designed to control two 20,000-kw units in the new Morgan Creek Steam Electric Station of Texas Electric Service Company. These boards are practically fabricated.

The next one is designed for control of one 60,000-kw unit in the new Handley Steam Electric Station of the same company. This one is ordered and has passed the drawing for approval stage.

The next four are designed for control of 60,000-kw units of the Middle South Utilities Corporation. These are to be located as follows: Two in the Hamilton Moses Steam Electric Station of Arkansas Power and Light Company; one in the Natchez Steam Electric Station of Mississippi Power and Light Company and one in the Ninemile Point Steam Electric Station of Louisiana Power and Light Company. These are ordered and have passed the preliminary drawing stage.

One is ordered for control of the 60,000-kw unit at Goldsboro Steam Electric Station of Carolina Power and Light Company.

Two more are being engineered for control of new 60,000-kw units.

Figure 1 of the discussion is a full-scale model which was made earlier and which is used as a standard with minor modifications for all subsequent jobs.

An Analysis of Transients and Feedback in Magnetic Amplifiers

WALTER C. JOHNSON
MEMBER AIEE

FRANK W. LATSON
STUDENT MEMBER AIEE

Synopsis: This paper presents an analysis of the steady-state and transient characteristics of the magnetic amplifier without feedback, with external feedback, and with one commonly-used type of self-feedback. Comparisons with experimental data indicate that the accuracy of the analysis is well within the limits that may be expected for nonlinear circuits.

THE terms saturable reactor, d-c controllable reactor, transductor, and magnetic amplifier have been used to denote an iron-cored inductor in which the a-c impedance can be controlled by magnetically saturating the core with an auxiliary d-c winding. In this paper, the term saturable reactor will be used to denote the iron-cored inductor itself, and the term magnetic amplifier will be applied to the entire circuit which makes use of the properties of the saturable reactor in order to amplify a signal. In many practical magnetic amplifiers, positive feedback is used to increase the amplification.

The steady-state characteristics of the saturable reactor have been discussed in many papers, and its properties have been related to the nonlinear characteristics of the core in a number of different ways by different investigators.[1-3] The purpose of this paper is to show how the steady-state characteristics of the saturable reactor, whether computed or determined experimentally, can be used to determine the effect of feedback on both the steady-state and the transient properties of the device. The illustrative computations given in this paper are based on the steady-state analysis given in reference 1, but the general methods can be applied equally well to the steady-state characteristics as found by any other means, including experimental methods.

Paper 50-94, recommended by the AIEE Electronics Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30-February 3, 1950. Manuscript submitted October 27, 1949; made available for printing December 2, 1949.

WALTER C. JOHNSON is Professor of Electrical Engineering with Princeton University, Princeton, N. J., and FRANK W. LATSON is with the Kellex Corporation, New York, N. Y.

The investigation presented in this paper was supported in part under a contract with the General Electric Company.

The Steady-State Load Line

A useful method of presenting the characteristics of a saturable reactor is to plot a family of curves of rms voltage across the reactor terminals versus either the rms or the average current through the reactor, one curve being given for each of a number of values of control current. An example of this is shown in Figure 1 for a commercial saturable reactor with a 4-legged silicon-steel core. This particular reactor was chosen for a number of these experiments because its comparatively large current-handling capacity facilitated accurate measurements of current and voltage. The quantity labeled I_m on the graphs is the net d-c magnetizing current referred to the control winding. For steady-state operation without feedback, this is equal to the control-winding current. The advantage of the type of presentation shown in Figure 1 is that it is not restricted to any particular value of supply voltage or to any particular value or type of load impedance. However, these graphs must be measured or computed on the basis of a particular waveshape of applied voltage, usually a sinusoidal one. The question is whether, because of the nonlinearity of the device, the curves so obtained can be applied to the operation of the reactor when connected to a load, for here the reactor voltage will not be sinusoidal.

When a saturable reactor is connected in series with a load impedance as shown in Figure 2, the load current will be small when the reactor is unsaturated. Then the voltage drop across the load will be small, and the reactor voltage will be nearly sinusoidal. On the other hand, when the reactor is saturated, the load current and load voltage will be large, and the reactor voltage will be nonsinusoidal. However, it has been shown previously[4] that, under the saturated condition, the characteristic curves of the reactor are affected only a little by the waveshape of the terminal voltage. Hence, we may expect that the characteristic curves will apply reasonably well to the loaded condition, and that a load line based on linear circuit theory can be traced on the characteristics of the reactor. The foregoing conclusion has been checked experimentally for various load lines on different reactors, and the results found to be uniformly satisfactory.

If the load impedance shown in Figure 2 is a resistance, and if the reactor is temporarily considered as a linear inductance, the relationship between the reactor voltage and the rms current is the ellipse

$$\left(\frac{E_s}{E_a}\right)^2+\left(\frac{I}{E_a/R_L}\right)^2=1 \qquad (1)$$

where

E_s = rms voltage across the saturable reactor
E_a = rms applied voltage
I = rms current in the circuit
R_L = load resistance

Thus, the load line is an ellipse with the intercepts E_a and E_a/R_L, as shown in Figure 3. The load line for a purely inductive load would be a straight line connecting the intercepts E_a and E_a/X_L, where X_L is the reactance of the load.

A typical calculated result, which was obtained with the load line of Figure 1, is shown in Figure 4. Comparison with the experimental points shows that the calculated result is reasonably accurate, particularly considering that the curves of Figure 1 were computed by the methods of reference 1 rather than measured.

Figure 1. Characteristic curves calculated for reactor 66G912; a-c coils in series. For parallel a-c coils, multiply abscissae by 2 and divide ordinates by 2

Figure 3. Load line for a resistive load

Transient Operation Without Feedback

This section presents an equivalent circuit for the computation of transients in the absence of feedback, and discusses the factors that influence the speed of response.

Calculated results are compared with experimental data.

Equivalent Control Circuit

When the a-c coils of the saturable reactor are connected in series, as shown in Figure 2, a change in the flux that links the control circuit will induce equal and opposite voltages in the two a-c coils, and these coils are therefore open circuited insofar as changes in the control circuit are concerned. The equivalent control circuit for this condition is shown in Figure 5(A) in which i_c represents the current in the control winding and ψ_e represents the flux linkage of this winding. The current in the control winding is here the only current that produces a d-c magnetomotive force, and so it is equivalent to the magnetizing current I_m of Figure 1.

When the a-c coils of the reactor are connected in parallel, they form a short-circuited coil around the control winding.[7] The resulting equivalent circuit, as obtained from the well-known coupled-circuit theory, is shown in Figure 5(B). In this circuit, R_{ac} represents the resistance of the series path through the two a-c coils, N_{ac} represents the number of turns on one a-c coil, and N_{dc} represents the number of turns on the d-c control winding (if the reactor is built with two separate cores, N_{dc} represents the number of control-winding turns on one core). The current i_m represents the magnetizing current that supplies the flux ψ_e, and i_i represents the effect of the current induced in the a-c coils. As before, i_c is the current in the control winding, but this now is equal to the sum of i_m and i_i.

Figure 5(C) shows the equivalent circuit for parallel-connected a-c coils, reduced to a more convenient form by Thévenin's theorem. The time lag introduced by the leakage fluxes is generally much smaller than that caused by the main control flux, ψ_e, and so, for simplicity, the leakage inductances have been neglected in the last diagram. The effective resistance for transient changes in i_m is the parallel combination of R_c and R_{ac}'.

Figure 2. Saturable reactor connected in series with a load impedance

Control-Circuit Flux Linkage

The transients caused by changes in the system will depend on the relation between the control-winding flux linkage, ψ_e, and the magnetizing current i_m. The main time lag is caused by the slowness of change of the flux that links the control winding, and so we shall assume that the steady-state load line is followed during transient conditions. The flux linkages of the control winding, as computed by the method of reference 1, are shown as dashed curves in Figure 1. By following along the load line, one can plot the relation between the magnetizing current and the flux linkage of the control circuit. This plot is shown in Figure 6 for the load line of Figure 1.

In using the universal curves of reference 1, it should be observed that the quantity plotted there is the d-c flux linkage of one a-c coil. This quantity must be multipled by two (because of the two a-c coils) and further multiplied by the turns ratio N_{dc}/N_{ac} to obtain ψ_e.

The foregoing graph of ψ_e versus i_m was drawn for a given load line. If a transient is caused by a sudden shift from one load line to another (change in applied voltage or in load impedance), the transition will take place along a line of constant ψ_e in Figure 1; this will determine the initial condition for the transient.

Figure 4. Load current versus control current along the load line of Figure 1

Figure 5 (left). Equivalent control circuits

Figure 7 (right). Time constant of reactor 66G912 for small changes in the neighborhood of 0.200 ampere control current

Transient Response

If the changes that take place are small enough in magnitude so that they traverse only a substantially linear segment of the control-circuit magnetization curve, the transient will be nearly exponential and a time constant can be defined. The average slope of the magnetization curve between the two points in question, expressed in weber-turns per ampere, is the effective inductance of the control winding, L_c henrys. The effective time constant is then L_c/R henrys, where R is the effective resistance of the control circuit as obtained from the appropriate equivalent circuit of Figure 5. For example, at a current of 0.2 ampere in Figure 6, the slope of the graph is approximately 41 weber-turns per ampere; that is, the effective inductance in the control circuit is 41 henrys. The effective resistance in the control circuit then determines the time constant. It will be observed in Figure 5 that, with series a-c coils, the time constant can be decreased indefinitely by increasing the resistance of the control circuit, R_c. But, with the a-c coils in parallel, the effective resistance for the transient is composed of R_c in parallel with R_{ac}', and so there is a lower limit for the time constant which is determined by R_{ac}'. This is illustrated in Figure 7, which shows calculated and experimental time constants for reactor *66G912* for small changes in the neighborhood of 0.2 ampere control current. As observed before, the effective inductance here is 41 henrys. The value of R_{ac}' was 209 ohms, and the resistance of the control winding itself was 127 ohms.

When the change in control current is so large that it involves considerable curvature in the characteristics, the transient will not be exponential and the concept of

a time constant loses much of its usefulness. In spite of this, it may sometimes be useful to estimate a mean value for the inductance and compute an approximate time constant. If more accurate results are desired, they can be obtained with a step-by-step integration of the magnetizing-current transient. A suitable graphical method is given in the Appendix. The results of a typical calculation, using this method, are shown in Figure 8 for parallel-connected coils. The magnetizing current was first determined as a function of time, then the load currents corresponding to various values of the magnetizing current were read from the load line of Figure 1. The load current was plotted in terms of peak values to facilitate comparison with an oscillogram. As shown by the equivalent circuit of Figure 5(B), the control-winding current is equal to the magnetizing current plus the induced current i_i. The latter can be found from the equivalent circuit when i_m is known as a function of time. The graph of actual control current in Figure 8 is rounded off slightly at the beginning. This is caused by the leakage inductance which was neglected in the calculations. The comparison between computed and experimental results in Figure 8 is typical of the many measurements that have been made.

Steady-State Operation With Feedback

Feedback circuits for the magnetic amplifier exist in great variety. Basically, the a-c load current is rectified and is applied to the magnetic core in such a way as to aid the saturation that is produced by the control current; in this way, the steady-state amplification can be increased to the point of instability. Figure 9(A) shows a magnetic amplifier with "external" feedback; that is, the feedback winding is separate from the load-current winding. Other magnetic amplifiers use "self" feedback, in which one set of windings serve as both load-current and feed-back windings. One of these circuits is shown in Figure 9(B). Since it is the average value of the rectified load current that is effective in feedback, the subsequent discussion will be based on the average-current characteristic curves of the saturable reactor. A set of average-current curves for reactor *66G912*, as computed by the methods of reference 1, are shown in Figure 10. The values of I_m on the curves are shown with ± signs because the reactor without feedback can not distinguish between the two directions of control current.

Load Line on an Average-Current Basis

If dry-plate rectifiers are used in the feed-back circuit, their characteristics can be approximated by a constant resistance in the forward direction. If this resistance is added to that of the load itself, the intercepts of the load line can be found as for the rms-current case, Figure 3, except that the intercept on the current axis is replaced by

$$\frac{E_a}{1.11\ R_L} \text{ average amperes}$$

where R_L is the apparent load resistance including the forward resistance of the rectifiers.

When gas-tube rectifiers are used, the voltage drop across each tube is nearly constant during conduction, and this introduces a further non-linearity into the analysis. Reasonable results are obtained by determining the intercepts of the load line as follows

$$\text{Voltage intercept} = E_a - V_t \qquad (2)$$

where V_t is the tube drop through the rectifier tubes that are instantaneously in series with the load: two tubes in Figure 9(A); one tube in Figure 9(B).

$$\text{Average-current intercept} = \frac{E_a/1.11 - V_t}{R_L} \qquad (3)$$

where R_L is the resistance of the load.

The load path can then be drawn as an ellipse between these intercepts. In the external-feedback circuit of Figure 9(A) the a-c coils can be connected either in series, as shown, or in parallel. The load line is then drawn on the appropriate characteristic curves. In the self-feedback circuit of Figure 9(B), the appropriate average-current curves are essentially the same as those of the parallel-connected reactor. Note, however, that there is no path for an induced circulating transient current, and so the equivalent circuit of Figure 5(A) is applicable for transients.

Effect of Feedback on Control Current

The effect of feedback will be expressed in terms of a feedback factor, β, which will be based on the magnetizing ampere turns that act on one core of a 2-core unit, or on one a-c flux path of a 3- or 4-legged single-core unit. It will be defined as the ratio between the d-c feedback ampere turns and the average a-c ampere turns, and will normally range between zero and unity.

Figure 14. Steady-state control characteristics for two transformers in external-feedback circuit

It will be convenient to base the formula for β on the total number of a-c turns in series between the a-c terminals of the complete reactor N_{ac}. This will be equal to twice the number of turns on one a-c coil for the series coil connection, and will be equal to the number of turns on one coil for the parallel connection.

If the a-c coils are connected in series, the number of a-c turns on one core will be $N_{ac}/2$. On the other hand, with a parallel connection, only half the average load current will flow through each coil. Hence, for either connection, the feedback factor can be written as

$$\beta = 2\frac{N_f I_f}{I_{av} N_{ac}} \qquad (4)$$

where

I_{av} = average value of the load current
I_f = d-c current through the feedback winding
N_f = number of turns on the feedback winding.

When two separate cores with separate magnetizing windings are used, the number of turns for either the control winding or the feedback winding should be counted on one core only, for two separate series coils could be replaced by one coil surrounding both cores.

With an external feedback circuit such as that of Figure 9(A), the d-c feedback current is equal to the average load current, and so the feedback factor is simply $2N_f/N_{ac}$.

For the self-feedback circuit of Figure 9(B), the same coils serve as both load and feedback windings, and so $N_{ac} = N_f$. The feedback current in each coil is half the average load current; hence, this circuit has the feedback factor fixed at the value $\beta = 1.0$.

The d-c magnetomotive force acting on the core now is made up of two parts, one arising from the control winding, and the other arising from the feedback winding. Thus, we have

$$N_{dc}I_m = N_{dc}I_{mf} + N_fI_f, \tag{5}$$

where

N_{dc} = number of turns on the control winding

I_m = magnetizing current required in the control winding in the absence of feedback, as obtained from the characteristic curves of the reactor

I_{mf} = magnetizing current required in the presence of feedback

N_fI_f represents the average ampere-turns supplied by the feedback

But, by the definition of β (equation 4), the last term of equation 5 can be replaced by $\beta I_{av}N_{ac}/2$, and so equation 5 can be written as

$$I_{mf} = I_m - \beta\frac{I_{av}N_{ac}}{2N_{dc}} \tag{6}$$

This equation can be used to compute the control current required to produce any given value of I_{av} along the load line. It was noted that the reactor without feedback cannot distinguish between the two directions of control current, and that the values of I_m assigned to the curves of Figure 10 can therefore be taken to be either positive or negative currents. For a given value of I_{av}, this produces two different values of I_{mf} from equation 6. The positive value of I_m corresponds to positive feedback; the negative value to negative feedback.

The variation of control current along any given load line, and the effect of different load lines, can be visualized by the method shown in Figure 11. Equation 6 can be written in the form

$$\alpha I_{mf} = \alpha I_m - I_{av} \tag{7}$$

where $\alpha = 2N_{dc}/\beta N_{ac}$. Figure 11(A) shows one of the characteristic curves of the reactor for a constant value of I_m. The intersection of this curve with the load line (point A) determines a value of I_{av} as shown. To find the corresponding value of control current, two lines are drawn on opposite sides of the vertical axis, each located αI_m units away as measured on the horizontal current scale. Then, as shown by equation 7, either of the lines A-B or A-C represents a value of αI_{mf} that will produce steady-state operation at point A on the load line. Both of these currents are shown negative in the drawing. Figure 11(B) shows a complete family of characteristic curves, and the horizontal arrows indicate the required values of αI_{mf} at various points on the load line. With zero control current, the circuit comes into steady state at the quiescent point where αI_m intersects the curve for I_m on the load line. This construction makes the effect of varying the load line especially easy to visualize.

The construction of Figure 11 shows clearly the requirement for a high amplification: namely, that αI_m shall be approximately equal to I_{av} over a large portion of the load line. This requires the proper choice of α, and also requires that the intersections of the characteristic curves with the load line should come at approximately equal intervals along the abscissae. The universal curves of reference 1 show that, if a saturable reactor has only a small "air-gap" line, the quantity I_mN_{dc}/N_{ac} is approximately equal to $I_{av}/2$ over a wide range. Then, if $\beta = 1.0$, we have $\alpha I_m = 2I_mN_{dc}/\beta N_{ac} \approx I_{av}$, which is the condition for a large amplification. With external feedback, this value of β must be obtained by an accurate control over the number of turns on the feed-back winding. With the self-feedback circuit of Figure 9(B), the value $\beta = 1.0$ is obtained automatically. The amplification of the device will be very sensitive to the value of β in the region of 1.0,[8] and the values slightly higher than this will produce a double-valued load-current characteristic, which may be useful in some applications.

Experimental Results

Experimental results for the self-feedback circuit of Figure 9(B) are shown in Figure 12, together with the corresponding computed values. The computations were made by applying equation 6 to the characteristic curves and load line of Figure 10, using $\beta = 1.0$. For example, at $I_m = \doteq 0.277$ ampere, the corresponding value of I_{av} in Figure 10 is 8.80 amperes. With $\beta = 1.0$, $N_{ac} = 230$ turns for one a-c coil, and $N_{dc} = 4{,}000$ turns on the control winding, equation 6 becomes

$$\begin{aligned} I_{mf} &= \doteq 0.277 - 0.500 \times 8.80 \times \frac{230}{4{,}000} \\ &= \doteq 0.277 - 0.253 \\ &= 0.024 \text{ ampere or } -0.530 \text{ ampere} \end{aligned}$$

These values, together with the value $I_{av} = 8.80$ amperes, determine two points on the solid curve of Figure 12.

The calculated results shown in Figure 12 are seen to check the measured values quite well. It should be observed, however, that a computational difficulty is encountered when β has a value which gives great sensitivity, and that this difficulty is the analytical counterpart of the sensitivity of the device to small changes in β. In this region, the required control current is obtained from equation 6 as the small difference between two comparatively large quantities; one subtracts amperes to obtain milliamperes. Hence, while the percentage accuracy with respect to I_m remains high, the percentage accuracy with respect to I_{mf} becomes poorer. This, of course, is a difficulty which must be expected of devices with large amounts of positive feedback. The accuracy of calculation could be improved by further refinements, but it is perhaps better to keep the computation to a minimum and to be content with a somewhat lower standard of accuracy here. A related phenomenon is the appearance of a hysteresis effect in the load current versus control current characteristic, as shown by the circles and crosses that mark experimental points taken in different directions in Figure 12. This effect is shown in greater detail by the graphs of Figure 13, in which the experimental data for small control currents are drawn to an expanded scale. Presumably the hysteresis was present when there was no feedback, but in the reactors we have tested the effect was so small in comparison with the normal currents that it was quite impossible to detect it with certainty. But with the feedback consistently subtracting a large fraction from the control current, the small remainder shows the hysteresis loop prominently. The large hysteresis effect seems to be characteristic of cores in which there is a portion of the d-c flux path that is not traversed by a-c flux. The 4-legged core used in reactor *66G912* was of this type.

Experimental results for external feedback that compare directly with the previous curves can not be given, as the reactor *66G912* did not have the required additional winding. Figure 14 shows a comparison between calculated and experimental results for a magnetic amplifier made up of two transformers. The feed-back winding was tapped, which made possible the use of several different values of β, and the graphs show the results for $\beta = 0$, 0.732, and 1.00. The computed curves were obtained by determining a set of characteristic curves similar to those of Figure 10, and then drawing a load line corresponding to the applied voltage and the load resistance. Equation 6 then was applied as illustrated previously for self feedback.

Transient Operation With Feedback

A given change in load current along a given load path corresponds to the same change in d-c flux regardless of the amount of feedback. For small changes in load current, the effective inductance of the control winding is

$$L = \frac{\Delta\psi_c}{\Delta i_{mf}} \tag{8}$$

where $\Delta\psi_c$ is the change in the control-winding flux linkage, and Δi_{mf} is the corresponding change in magnetizing current with feedback. The application of feedback reduces Δi_{mf} for a given $\Delta\psi_c$, and so increases the inductance seen by the

Figure 16. Graphical construction for a single step

Figure 17. Sequence of graphical constructions

control circuit. If the same resistance is maintained in the control circuit after feedback is applied, the time constant L/R_c will be increased proportionately to the amount that the sensitivity of the amplifier is increased. To keep the time constant the same after feedback is introduced, the control-circuit resistance must be increased. The effect can be shown as follows

$$\text{Time constant: } t_c = \frac{L}{R_c} = \frac{\Delta\psi_c}{R_c \Delta i_{mf}} = \frac{\Delta\psi_c}{\Delta e_c} \quad (9)$$

For small changes along any given part of the load path, the time constant varies inversely with the required increment in control-circuit voltage, Δe_c. If R_c is increased in the same proportion as Δi_{mf} is reduced, both Δe_c and the time constant will remain constant. The sensitivity to changes in control current now is greater than without feedback, but the sensitivity to changes in control voltage is the same as before.

Analysis

The computation of transients in the feedback amplifier follows the same principles outlined earlier for the magnetic amplifier without feedback. The main difference is that the feedback changes the control current for a given control-winding flux linkage so that Figure 6 no longer applies. A graph of flux linkage versus control current is given in Figure 15 for reactor *66G912* operating in a self-feedback circuit. This graph is obtained by reading the flux linkage at various points on the load line of Figure 10, and then referring to Figure 12 to find the corresponding control-winding currents.

The time constant for small changes can be found as described for the reactor without feedback. An equivalent inductance is first found for the control winding, by determining the slope of the flux-linkage graph in weber-turns per ampere. For example, for a change in control current from zero to 9 milliamperes, the flux linkage in Figure 15 changes almost linearly from 8.2 to 12.9 weber-turns. The mean inductance here is approximately

$$L \approx \frac{\Delta\psi_c}{\Delta i_{mf}} = \frac{12.9-8.2}{9\times10^{-3}} \approx 520 \text{ henrys}$$

It is important to realize that, because of the inherently smaller accuracy in computing control currents for large amounts of feedback, and because of the uncertainty introduced by the hysteresis effect, the foregoing calculation has a lower accuracy than the corresponding one without feedback. The time constant is observed experimentally to depend to some extent on the direction of change of the current and on the direction and magnitude of previously existing control currents, as would be expected from the hysteresis loops of Figure 13. Using the foregoing calculated value of inductance, a resistance of 139 ohms in the control circuit would produce a time constant of $L/R_c = 520/139 \approx 3.7$ seconds in the region between zero and 9 milliamperes control current. An oscillogram of a transient between these two points showed an approximately exponential variation which had a time constant of about 3.3 seconds. This result, with the calculated value 12 per cent higher than the measured value, is typical of the time constants that have been checked. The error has generally been of the order of 10 to 15 per cent, with the calculated result being high. It should be emphasized that the foregoing results were computed by starting with the a-c saturation curve of the core, and that no experimental corrections were used at any stage of the calculations.

Table I

Control Current, Amperes	Time Constant, Seconds Calculated	Measured
Zero (rising)	2.1	1.9
0.25 (rising)	1.7	1.5
0.23 (falling)	1.7	1.5
0.50 (falling)	1.4	1.2

If desired, the path of a transient that spans a markedly nonlinear portion of the flux-versus-current graph can be computed graphically by the step-by-step method described in the Appendix. The main error here is caused by the uncertainty introduced into the initial condition by the hysteresis effect.

If a comparatively large control voltage is used to force the control current to change rapidly to a point well above the knee of the control-circuit magnetization curve, the $i_m R_c$ drop can be neglected during most of the change in flux, and the time required for the flux linkages to change an amount $\Delta\psi_c$ is only slightly greater than $\Delta\psi_c/E_c$, where E_c is the suddenly-applied control voltage. For example, reactor *66G912* connected in the self-feedback circuit was started at $\psi_c = 6$ weber-turns ($I_{av} = 0.8$ ampere), and an electromotive force of 47 volts was suddenly applied to the control winding. This was sufficient to produce a steady-state control current of 300 milliamperes, which is well above the knee of the curve of Figure 15; see also Figure 12. The final value of ψ_c is, from Figure 15, about 21 weber-turns ($I_{av} = 10.2$ amperes). Therefore, the approximate time of rise is $\Delta\psi_c/E_c = (21-6)/47 = 0.32$ second. An oscillogram showed that the load current rose almost linearly to 10 amperes in 0.31 second.

Calculations similar to the foregoing

ones also have been made for the external-feedback circuit whose steady-state control curves are given in Figure 14. A typical comparison between computed and measured time constants for a feedback factor of 0.732 is given in Table I. These experimental data were obtained by applying a control-circuit voltage of moderate size and measuring on an oscillogram the instantaneous values of di/dt at various instantaneous control currents.

Appendix. Graphical Computation of Nonlinear Transient

A graphical method now will be described for the step-by-step integration of a nonlinear differential equation of the form

$$\frac{d\psi}{dt}+Ri=E \tag{10}$$

where ψ is a nonlinear function of i. Expressed approximately in terms of finite differences, equation 10 is

$$\frac{\Delta\psi}{\Delta t}+Ri=E \tag{11}$$

This equation can be rewritten in the form

$$\frac{\Delta\psi}{E/R-i}=R\Delta t \tag{12}$$

Now consider Figure 16, which shows a graph of the function $\psi(i)$. A vertical line is erected on the i-axis at the value E/R, and a second vertical line is erected at the value $E/R+K$, where K is any convenient number, either positive or negative. (For a current rising from zero to the value E/R, a convenient value of K is E/R. For a current dropping toward zero, a convenient value of K is the negative of the initial value of the current.) Imagine that the graph of ψ versus i is made up of small steps, as shown in the figure. Consider the step whose vertical height is labeled $\Delta\psi$, and the point P which is located anywhere on the vertical line that was erected at $i=E/R$. A straight line is drawn from the top of the step through the point P, and is extended to the second vertical line. A second straight line is drawn from the bottom of the step through the point P, and is extended to the second vertical line. The two shaded triangles formed by this construction are similar, and so we have

$$\frac{\Delta\psi}{E/R-i}=\frac{h}{K} \tag{13}$$

where h is the height of the right-hand triangle measured on the ψ-scale. Comparison with equation 12 shows that the time required for the change $\Delta\psi$ is given by

$$\Delta t=\frac{h}{KR} \tag{14}$$

The location of the point P is immaterial, and so is the value of K except that it should lend itself conveniently to the scale of the drawing.

In order to determine the complete path of a transient, it is necessary to add the amounts of time for each step in the graph, starting with a known initial current. The addition can be done graphically as shown in Figure 17, which assumes for purposes of illustration that the current starts initially from zero. The construction lines are drawn in the sequence 1,2,3,4,... The first is drawn from the top of the first step so that it intersects the right-hand vertical line at zero on the ψ-scale. This establishes the point P_1, and the second construction line is drawn from the bottom of the first step through this point. The height h_1 determines the time required for the current to reach the value i_1 (see equation 14). The construction proceeds upward step by step, and, at any point, the net height h_k determines the time required to reach the corresponding current i_k: $t_k=h_k/KR$.

The foregoing method can be used for computing either increasing or decreasing transients, starting with any initial value. For increasing currents, the quantity $E/R-i$ in equation 13 will be positive, and K should be a positive quantity for convenience. For decreasing currents, $E/R,-i$ will be negative, and the construction is generally more convenient with K chosen as a negative quantity.

Discussion

L. A. Finzi (Carnegie Institute of Technology, Pittsburgh, Pa.): The analysis of the transient response of magnetic amplifiers with feedback presented in this paper implies that the coupling between signal windings and feedback windings is neglected. Actually changes of direct components of core fluxes, that follow any variations of the signal, induce in the feedback windings voltages which do not cancel, as is the case, for example, in series-connected a-c windings of simple amplifiers without feedback. For instance, in an amplifier with positive feedback a decrease of the signal induces in the feedback windings a voltage acting in the direction of rectifier conduction. Therefore, at least in some portions of the cycle, induced currents flow in the feedback windings and the transient response, according to Lenz's law, is delayed in a manner similar to the one observed in no-feedback amplifiers with parallel connected a-c windings. As a matter of fact, voltages induced in opposition to the direction of rectifier conduction, as they arise for instance for an increase of signal in amplifiers with positive feedback, also affect the transient response as they act against the flow of feedback currents that would be expected from simple steady-state considerations.

It is conceivable that these induced voltages in some instances may be small in comparison with the crest of the voltage impressed by the a-c source across the feedback rectifiers; then, of course, the simplifying assumption implied may be acceptable. On the other hand, however, the very nature of the feedback action, as recognized also by Johnson and Latson in their paper, is based on a very sensitive balance among ampere-turns of the various windings and simplifying assumptions concerning instantaneous values of currents in the feedback windings have to be weighed very carefully.

Walter C. Johnson and **Frank W. Latson**: As Mr. Finzi states, the signal and feedback windings are magnetically coupled, and a change in signal will induce a voltage in the feedback winding. The main question is the order of magnitude of this voltage as compared with the other voltages existing in the same circuit.

If the voltage across the control winding is suddenly changed an amount Δe_c, a voltage approximately equal to $N_f\Delta e_c/N_{ac}$ will be induced in the feedback winding, where N_f is the number of turns on the feedback winding and N_{ac} is the number of turns on the control winding. The voltage in the feedback circuit with which this should be compared will depend on whether or not the load impedance is included in the circuit in which this voltage acts. The magnitude of Δe_c itself will depend on whether the amplifier is used in a continuous-type control such as a servomechanism or whether it is used in an on-off type of application.

In the circuit of Figure 9(A), the rectifiers that are not conducting are biased off by a voltage that is equal to the normal voltage drop through the feedback winding plus the forward voltage drop in one rectifying element. A decrease in signal will induce a voltage in the feedback winding that is in the proper direction to produce a short-circuit current through two rectifier elements, but this path will be inoperative

unless the induced voltage exceeds the bias voltage across the nonconducting rectifier element. Otherwise, the voltage induced in the feedback winding acts in series with the load, and its effect in the circuit can be judged by comparing it with the applied electromotive force, E_a, or with the normal load voltage. An increase in signal results in an induced voltage that does not tend to produce a short-circuit current through the rectifiers, and which therefore always acts in series with the load. For the circuit of Figure 9(B) or for a circuit similar to that of Figure 9(A) but with the load directly in series with the feedback winding, there is no potential short-circuit path for either direction of signal change, and the induced voltage acts in series with the main applied electromotive force.

Therefore, the voltage induced in the feedback winding should be compared with two other voltages. The first comparison will be with the normal voltage existing across the feedback winding, to determine whether short-circuit conduction is likely to occur for decreasing signals in the circuit of Figure 9(A). The second comparison will be with either the applied electromotive force or the normal load voltage to determine the effect of the induced electromotive force in the absence of a short-circuit path.

The ratio of the induced voltage in the feedback winding to the normal voltage drop through the winding can be written as

$$\frac{\text{Induced voltage}}{\text{IR drop}} = \frac{\Delta i_c N_f}{I_L R_f N_{dc}} = \frac{\Delta i_c R_c N_f}{I_L R_f N_{dc}} \qquad (1)$$

where Δi_c is the eventual change in control-winding current, R_c is the resistance of the control circuit, I_L is the average load current, and R_f is the resistance of the feedback winding. If we assume that the load and feedback windings operate at the same current density and have approximately the same mean length of turn, we have very nearly $R_f \approx R_{ac} N_f / N_{ac}$. Also, if the control and load windings occupy approximately the same amount of space, we shall have very nearly $k R_c / N_{dc}^2 \approx R_{ac} / N_{ac}^2$, where k is the fraction of the control-circuit resistance that is contained in the control winding itself. Making these substitutions into the foregoing ratio, we find its order of magnitude to be

$$\frac{\text{Induced voltage}}{\text{IR drop}} \approx \frac{\Delta i_c N_{dc}}{k I_L N_{ac}} \qquad (2)$$

In a magnetic amplifier with positive feedback, the ampere-turn ratio $\Delta i_c N_{dc} / I_L N_{ac}$ will be very much less than unity. Unless the fraction k is made very small by the use of an extremely large "forcing" resistor, the foregoing ratio will be small. This indicates that short-circuit conduction through the rectifiers of Figure 9(A) is likely to occur only for very short intervals during the cycle, and then only in the case of decreasing signals of large magnitude.

Generally, then, the voltage induced in the feedback winding will be forced to act in series with the load, and its effect can be judged by comparison with the normal load voltage. To obtain the ratio of the induced voltage to the normal load voltage, we multiply the ratio (2) by R_f / R_L. Using the former approximation $R_f \approx R_{ac} N_f / N_{ac}$, we obtain

$$\frac{\text{Induced voltage}}{\text{Load voltage}} \approx \frac{1}{k}\left(\frac{\Delta i_c N_{dc}}{I_L N_{ac}}\right)\left(\frac{R_{ac}}{R_L}\right)\left(\frac{N_f}{N_{ac}}\right) \qquad (3)$$

As was observed previously, the ampere-turn ratio is generally much smaller than unity.

The third factor, R_{ac}/R_L, is the per-unit resistance of the load winding, and is a very small fraction. The last factor, N_f/N_{ac}, will rarely exceed unity. Hence, the ratio will almost always be a very small quantity indeed, and the effect of the induced voltage will be inappreciable.

To take a specific example with some moderately unfavorable data: consider the reactor *66G912*, which was used in some of the experiments described in the paper. As shown in Figure 12, a load current of 9 amperes is produced by a control-winding current of approximately 30 milliamperes. The resistance of the control winding itself was 127 ohms. Assuming an external forcing resistance of 373 ohms, the total control-circuit resistance would be 500 ohms. The required control-circuit electromotive force for this condition would be $0.030 \times 500 = 15$ volts. Assuming that the amplifier is initially in a quiescent condition and that this voltage is applied suddenly in the control circuit, and using the values $N_{ac} = 230$, $N_c = 4{,}000$, we compute the induced voltage in the feedback winding to be

$$15 \times 230/4{,}000 = 0.86 \text{ volt}$$

The value of the peak of the impressed electromotive force here is about 162 volts, which is nearly 200 times a s large. A smaller external resistance in the control circuit, or a smaller change in control voltage, will produce a correspondingly larger ratio.

The conclusion is that the voltage induced in the feedback winding by changes in the signal voltage will not generally be a factor of major importance.

A Magnetic Amplifier Frequency Control

L. J. JOHNSON

H. G. SCHAFER
NONMEMBER AIEE

Synopsis: A frequency control system utilizing a magnetic amplifier is described. The frequency control is applied to a dynamotor where the accuracy must be ±0.1 per cent over a range of temperature, input voltage, and load. A qualitative description of the system is given, along with performance data gathered from tests on a prototype model.

FOR the operation of certain types of equipment aboard ship, an accurate source of frequency-regulated alternating current is required. This need has been met by the use of small motor-driven alternators or dynamotors of 1-kva capacity or less. These alternators run on the ship's d-c power supply, and frequency control is accomplished usually by a frequency-sensing device and a servomechanism, which, in turn, control the motor field current and the frequency.

Electromechanical control systems have some disadvantages, the most important of which are vacuum-tube amplifiers and moving mechanical parts. These systems also are slow in response and sensitive to shock and vibration.

In order to overcome the limitations of existing frequency regulating devices, the magnetic-amplifier type regulator described herein was developed. This new regulator system has no moving parts, is extremely accurate in performance, and is not affected by shock and vibration.

Description

General—A magnetic amplifier frequency control is shown in the schematic diagram of Figure 1. The system consists of the following components:

A. A dynamotor for d-c to a-c conversion. (In this particular system, the dynamotor output rating is 80 volt-amperes at 115 volts and 60 cycles. The d-c voltage supply is 115 volts.)

B. A small permanent magnet a-c pilot generator attached to the dynamotor shaft.

C and *D*. A pair of series resonant circuits with bridge rectifiers.

E. A magnetic amplifier, consisting of two toroidal reactors and two self-saturation rectifiers.

F. A control field rectifier.

Operation

In operation, two series resonant circuits (*C* and *D*) are excited by the output of a pilot generator (*B*), and supply rectified control currents to the magnetic amplifier (*E*). The magnetic amplifier controls the current flow to the control field rectifier (*F*), which, in turn, supplies rectified current to the control field of the dynamotor.

The circuit components (*A* to *F*) in Figure 1 comprise a closed servomechanism loop. In addition to the principal circuit components, an electrical damping circuit is utilized, and consists of capacitor C_1, and two auxiliary windings on the magnetic amplifier cores. The purpose of the damping circuit is to achieve high stability together with high sensitivity.

Two frequency-sensing circuits, shown at (*C*) and (*D*) in Figure 1 are used to maintain the system at constant frequency. These circuits are tuned above and below the 240-cycle pilot generator frequency as shown in Figure 2.

The system operates at the cross-over point of the two resonance curves, and this point is accurately maintained by the use of temperature-stable circuit components. The use of a 240-cycle pilot generator and corresponding resonant circuits for frequency sensing has two important advantages, namely:

1. The size of the resonant circuit com-

Figure 4. Temperature characteristics of the magnetic amplifier and dynamotor at various temperatures, loads, and supply voltages

ponents can be made smaller than those required for 60 cycles.

2. The frequency-sensing circuits are independent of the voltage regulation of the main alternator.

The type of core material used in the resonant circuit inductors has an important effect on the stability of the system. The most stable reactors were wound on Permalloy dust toroidal cores, known as *Mu-125* material. The capacitors used were of a high grade mica type having a small temperature coefficient.

The Magnetic Amplifier

Referring to Figure 1, the magnetic amplifier component, E, of the system is seen to consist of two saturable reactors, each of which has one power winding, two control windings, a damping winding, and two half-wave selenium rectifiers for self-saturation.

The directions of the magnetic fluxes are as indicated by the arrows on the diagram. When the outputs of the two frequency-sensing rectifiers are equal (at a dynamotor frequency of exactly 60 cycles) the ampere-turns in the control windings are equal and opposite. Any disturbance of the ampere-turn balance in the control windings due to a change in frequency will cause the reactance of the magnetic amplifier to increase or decrease as a function of the net control currents delivered by the sensing circuits. The magnetic amplifier reactors in turn regulate the current to the control field coils of the dynamotor in such manner as to restore the frequency to normal value.

The Anti-Hunt Circuit

The anti-hunt or transient-feedback circuit (damping winding), shown in Figure 1, consists of a large capacitor C_1 and a winding on each of the saturable reactors of the magnetic amplifier. This anti-hunt circuit is connected in parallel with the control field winding and produces a magnetomotive force in the magnetic amplifier which is a function of the rate of change of voltage across the rectifier. This additional magnetomotive force acts in a direction to stabilize the frequency of the system.

Design Requirements

The operating requirements for this regulated a-c power supply dictated the following specification limits:

1. A magnetic amplifier control having no moving parts should be ultimate objective.

2. The control system should maintain a constant frequency within ±0.1 per cent, with a load variation of 100 per cent, and an input voltage variation of ±5 per cent.

3. The equipment should operate at ambient temperature varying from 40 to 130 degrees Fahrenheit.

4. Because of the small size of the machine to be regulated, the efficiency of the regulator system should be kept high.

5. In order to keep the power rating of the amplifier at a low value the shunt field of the dynamotor should be designed to incorporate a separate control field in conjunction with a fixed shunt field. By this means, the control field power only would be regulated by the magnetic amplifier. As a means to reduce further the burden on the control field and the amplifier, the dynamotor should be designed to incorporate a differentially compound winding to give good speed regulation without external control. The frequency control need then be only large enough to compensate for the deficiency of the differentially compounded motor as a constant speed device. A centrifugal switch was used to by-pass the differential field during the starting period.

Performance Results

A detailed description of the design procedure for each of the components involved in this control system is beyond the scope of this paper. It is believed, however, that the evaluation data shown in Figures 3 and 4 will be an indication of the kind of results to be expected from this and similar systems.

Temperature Stability

A test on the complete system enclosed in a temperature cabinet gave the results shown in Figure 3 at 115 volts input and

Figure 3 (below). Temperature characteristic of the magnetic amplifier and dynamotor at normal load and supply voltage

Figure 6 (above). Oscillogram of transient current in the dynamotor control field, (A) upon application of a 60-watt a-c load, and (B) upon removal of load from dynamotor

Figure 7 (right). Oscillogram of current in the damping circuit, (A) upon application of a 60-watt a-c load, and (B) upon removal of load from dynamotor

80 watts output. At other supply voltages, the frequency error is as shown in Figure 4. It may be noted that at no time did the error exceed 0.1 per cent, and at the more usually encountered ambient temperatures the frequency error was 0.05 per cent or less.

Transient Response

The effectiveness of the control in quickly restoring stable operation after an external disturbance to the system is shown in the oscillograms of Figures 5 to 7. The two oscillograms in this Figure 5 show the rectified control current in the higher frequency resonant circuit. Since this current is a function of frequency, it is used to indicate the transient departure from the normal frequency. In Figure 5(A) the oscillogram shows the effect of suddenly applying an a-c load of 60 watts with the dynamotor running initially at zero load. When there is a drop in speed, the operating point in Figure 2 moves downward on the higher frequency resonance curve. On the other hand, when the load is suddenly removed, the frequency of the machine rises and the control current responds as shown in Figure 5(B). It may be noted that the normal 60-cycle frequency is restored approximately two-thirds of a second after the beginning of the disturbance. Most of this time delay can be attributed to the inertia of the dynamotor. Figure 6 shows the current surges in the control winding of the dynamotor when a 60-watt load is suddenly applied and removed. Figure 7 shows oscillograms of the currents in the anti-hunt winding when a 60-watt load is applied and removed.

Figure 8. Assembled magnetic-amplifier frequency-control unit and dynamotor

Figure 8 shows a view of a completed magnetic amplifier frequency control unit. This particular unit is enclosed in a watertight case for shipboard installation.

Conclusion

An example of a successful magnetic amplifier design has been given in this paper.

The system described is believed to be smaller, lighter, and more effective than other frequency controls designed for the same purpose. At normal temperatures the system gives frequency regulation of the order of one part in 5,000 or better. This accuracy of performance is achieved without the aid of a tuning fork or quartz crystal.

No Discussion

Dielectric-Recovery Characteristics of Power Arcs in Large Air Gaps

G. D. McCANN
FELLOW AIEE

J. E. CONNER
NONMEMBER AIEE

H. M. ELLIS
STUDENT MEMBER AIEE

Synopsis: A satisfactory test technique has been developed for studying the rates of dielectric recovery of large air gaps and other types of power-system insulation. This permits the accurate control of the fault conditions so that all practical types of fault currents can be studied. These are: (1) very high magnitude short-duration surges typical of lightning currents; (2) currents of power-system frequencies; and (3) intermediate duration currents such as those which might result from high-frequency current zeros produced by natural system oscillations.

Results are presented showing the rate of dielectric recovery of 3-, 6-, and 11-inch standard rod gaps for power frequency fault currents up to 700 amperes. Electrode cooling effects were found important at 3-inch gap spacings but not at six inches or above. The 11-inch gap data are proportionately higher than the 6-inch data, indicating that the results can be extrapolated. The data show that for arcs of a few cycles actual duration has little effect on rate of recovery. A range of current magnitudes from 50 to 700 amperes causes only about a 2-to-1 variation in rate of recovery. For the normal ratios of transmission-line insulation level to operating voltage (about four to one) minimum delay times of from 0.025 second for 100-ampere faults to 0.05 second for 700 ampere faults are required before the recovery voltage reaches the magnitude of the normal applied voltage. Time intervals of 0.05 to 0.08 second are required before the voltage strength has built up to twice this level or one-half the initial gap strength. This is contrasted with a corresponding time interval of only 2- to 3,000-microseconds for very short duration lightning-surge currents.

High-speed camera studies of the arcs show that for power-frequency faults of one-half to one-cycle duration, visible luminous gases are present in the gap space for times after current zero up to 0.07 or 0.08 second. The illustrations and voltage breakdown curves show that subsequent breakdowns will occur through the region of brightest photographic luminescence if such still exists in the gap space. Under these conditions breakdown is started by initial streamers from each electrode which, however, propagate at much slower velocities than for breakdown of air under normal conditions. Time intervals as high as 30 or 40 microseconds are required for a low-impedance path to be established.

This research program is being extended to other insulating media and fault conditions and fundamental studies are being made of the dielectric-recovery mechanism.

KNOWLEDGE of the dielectric-recovery characteristics of power-system insulation following flashover or breakdown is of fundamental importance in determining and improving power-system performance. However, relatively little fundamental data have been obtained because of the complexity of the phenomena and the difficulty of performing significant tests on representative insulation media. The bulk of the data that have been gathered apply only to the circuit breaker arc or to small gaps where electrode effects dominate.

Studies of the primary insulations are important in determining probabilities of insulation failure resulting in sustained faults, permissible reclosing times for circuit breakers, and the performance of disconnect switches. A study of the performance of simultaneous arcs through similar and dissimilar insulating media and at various distances apart on systems is required for better co-ordination of such protective devices as deion protector tubes. Dielectric-recovery studies are also of great importance in determining the characteristics of system transients during such faults as arcing grounds. The conditions under which arc extinction and reignition occur determine the characteristics and magnitudes of the resulting system transient voltages. Of particular importance in this connection are the conditions under which current zeros can be forced in arc extinction with the resulting high voltages.

Recognizing this to be a general field of considerable importance at the present time, a co-operative research program on dielectric recovery has been instigated at the High Voltage Laboratory of the California Institute of Technology. This program is being sponsored by the Department of Water and Power of the City of Los Angeles, the Kelman Electric and Manufacturing Company, and the Southern California Edison Company. The first phase of this program, discussed in this paper, deals with air insulation at normal atmospheric conditions. This medium was chosen first since it is the most fundamental one of the practical insulations and is subject to the least number of controlling factors. A limited amount of data had been obtained elsewhere on large air gaps[1,2] by artificially producing faults and determining system conditions under which reignition did or did not occur. Also safe circuit-reclosing times have been determined from staged tests under a limited range of conditions.[3,4] Such techniques, however, permit a very limited variation in the important parameters and require so long that either insufficient data are obtained or important variations have occurred in the conditions during the period of the test. Also many such staged tests are performed by closing in on an artificially produced or fused fault. Accurate timing of the start of the fault current thus is not obtained, and vaporized metal may be produced in the gap by the fused element.

A testing technique has been developed

Figure 1. Schematic diagram of dielectric-recovery test circuit

which overcomes these difficulties and is an extension of work performed earlier on lightning current faults.[5] The insulation medium is first broken down by a surge generator, the fault current allowed to flow a specified time and then shut off, after which the dielectric strength of the insulating medium is tested over a wide range of time delays with a second surge generator. By this means data for complete dielectric-recovery curves can be obtained for a wide range of fault-current magnitudes and durations. Because of the very flat breakdown characteristics of air insulation, particularly while still under the influence of a predischarge, such data are applicable to all practical types of system overvoltages. This technique permits the accumulation of a large mass of data so that effects of the various important parameters can be studied and quantitative correlations made with theoretical approaches to the problem.

Test Circuits and Techniques

The main test and auxiliary control circuits are of interest not only because they represent a new technique for studying dielectric-recovery phenomena, but also because of certain new control methods that are being applied to surge-generator testing. A general schematic diagram of the test circuit is shown in Figure 1. Figure 2 shows the main power circuit. This part of the test circuit is shown by heavy lines in Figure 1. Sixty-cycle power is supplied from a 17-kv bus through a single-phase induction regulator. This energizes a bank of four 150-kva 8.6- to 2.4-kv transformers which supply the actual test circuit. By various combinations of series or parallel connections a range of power currents and voltages can be supplied to the test gap. A further fine control of the fault current is obtained with the current-limiting inductor which can be varied in approximately one-ohm steps up to 60 ohms. Fault currents up to approximately 3,000 amperes can be obtained. The ignitron circuit shown in Figure 1 is used to control the fault-current duration if the self-extinguishing characteristics of the circuit are not to be studied directly.

To start a fault condition, the test gap is first broken down by the surge generator designated as Number 1. Its firing time is accurately synchronized with the main 60-cycle power source by means of the phase-shifting selsyn peaking-transformer trip circuit shown in Figure 3. Thus fractions or multiples of half-cycles of fault current can be accurately duplicated. As shown in Figure 3, radar pulse transformers, rated 8 to 30 kv, have been used with excellent results for tripping the surge generators.

The facilities of the California Institute of Technology High-Voltage Laboratory include two 100-kv surge-generator charging circuits and two separate 10-bank, 1,000-kv surge generators that can be used as two separate generators or as one 2,000,000-volt generator. In this test the two separate units comprised generators Numbers 1 and 2.

When the main 60-cycle power circuit of Figure 1 is energized, the test-gap shunt resistors are isolated by means of a small air gap to reduce their required power rating. For breaking down the test gap, surge generator Number 1 is adjusted to cause gap flashover on the wave front and thus produce a very short duration voltage pulse which (due to its high effective frequency) can be kept out of the main power circuit by means of the filter circuit shown in Figure 1. The inductor and capacitors of this circuit are shown in Figure 2 together with the test-gap and power transformers. At high frequencies this circuit is a high impedance as viewed from the test gap and thus permits sufficient voltage from surge generator Number 1 for gap breakdown in short times, but allows very little voltage to reach the transformer terminals.

With the use of only the one surge generator and by blocking cut-off of the ignitron circuit, it is possible to study directly the reignition characteristics of the test gap over a limited range of system recovery voltages and frequencies, as indicated by the range of variation of voltage and filter-circuit constants shown in Figure 1. Natural system frequencies from 300 to 7,000 cycles per second can be obtained.

The Number 2 surge generator is used for the second type of dielectric-recovery study in which the insulation strength of the test medium is tested at various time intervals following the end of a controlled fault current. The Number 2 surge generator and ignitron circuit are both timed by a pulse taken from the Number 1 generator as shown schematically in Figure 1. The ignitron bias control and timing-control circuits are shown in Figure 4. The pulse from the Number 1 generator is applied to a single-shot multivibrator circuit whose time delay in sending out a pulse can be controlled by the variable capacitor shown. This pulse is applied to the grid of a *2050* thyratron whose plate circuit supplies current to high-speed relays in the bias-control circuits of the *F6105* ignitron control thyratrons, see Figure 4. These relays have a delay time of only five milliseconds so that the ignitron circuit can cut off the fault current at any desired current zero. For fractions of a half-cycle it was found readily possible to trip the *F6105* grid-bias circuit by an induced pulse from the Number 1 generator. Thus the ignitrons are immediately conditioned to block off at the first current zero. The duration of fault current then is varied by the initial trip time of the Number 1 generator.

Figure 4. Timing and bias-control circuits for main ignitron fault-duration control circuit

Ten-Stage Scale-of-Two Counting Circuit

It is desired, of course, to control accurately the time of firing of the Number 2 surge generator to study the dielectric-recovery properties of the test medium over a wide range of times after the end of the fault current. For this purpose a binary or scale-of-two flip-flop circuit[8] was developed which counts pulses from a variable frequency square-wave generator. This circuit is shown in Figure 5 with its schematic diagram in Figure 6.

Each stage of the counting circuit consists of two tubes which have two stable states and can be changed from one to the other by the appropriate trigger pulse, the two stable states being distinguished by which tube is conducting. The terminal Out of one scale-of-two is connected directly to the terminal In of the next scale-of-two and so on for 10 stages. When *T-2*, Figure 6, of the preceding stage becomes conducting, a negative signal is applied to the plate of the Off tube and through the resistance-capacitance cross coupling to the grid of the On tube, which causes the flip-flop to pass to its other stable state. When *T-2* of the preceding state becomes nonconducting the resulting positive pulse has no effect on the following scale-of-two. Each scale-of-two produces one negative pulse for each two that are applied to it from the preceding stage, so that for 10 stages a total of 2^{10} or 1,024 pulses input to the first stage is required to produce a complete operation of the counting circuit. Thus, by varying the frequency applied to the counting circuit a varying time delay can be obtained. The oscillator driving the square-wave generator will apply frequencies up to 80 kc, and thus for 10 stages time delays from over one minute and down to about 13,000 microseconds can be obtained. Less stages are used for shorter delays. Values less than 100 microseconds can be reproduced.

The counting circuit is triggered by a pulse from the firing of the first surge generator which changes the stable state of the *6SN7* gate control tube, thus putting a positive bias on the *6SJ7* amplifier tube and allowing this tube to supply square waves to the first scale-of-two. The stable state of the gate-control tube is returned again to its cut-off state by a negative pulse from the counting circuit

Figure 3 (below). Control pulse circuits for timing surge-generator trip circuits

Figure 5 (right). View of timing control circuit for the number 2 surge generators showing oscillator, square wave generator, and binary counting or delay circuit

Figure 6. Schematic diagram of timing control circuit for number 2 generator

at the end of its operation which in turn negatively biases the *6SJ7* to cut-off and resets the counting circuit for its next operation. The control pulse out of the counter is fed to the Number 2 surge-generator trip-pulse circuit shown in Figure 3.

Automatic Fuse Changers

Although the inductance-capacitance filter of the main power circuit, Figure 1, presents sufficient impedance for the short-duration pulse of the Number 1 generator, it is not very practical to have a filter of sufficient impedance to allow a conventional surge generator to produce a full wave with a tail of 40 microseconds or more. It was found quite easy, however, to use a series-fused gap so co-ordinated as to allow the fault current to flow but to insulate against the discharge of the Number 2 generator. An automatic fuse changer was developed to allow continuous operation without shutting off the main power circuit between test shots. This is shown in Figure 7. The device pulls a small diameter copper wire from a spool around and between gap terminals at the top. The fuse holder is driven through an insulated shaft by a limit-switch position-controlled motor that accurately positions each quarter-turn of the fuse-holder rotor.

Recording Equipment

The complete circuit is suitable for testing insulating media with initial insulation levels up to about 300 or 400 kv. As shown in Figure 1, shunts are used for measuring the gap current and voltage. Low-frequency records are obtained with a magnetic oscillograph and high-speed records with a Westinghouse cold-cathode cathode-ray oscillograph with both electrostatic sweep control and a high-speed drum-type film holder. The cathode-ray oscillograph can be tripped from the Number 1 or Number 2 generator as desired. In addition, photographic studies of the arc path can be made with two cameras; a high-speed (3,000-frame-per-second) Eastman prism shutter-type 16-millimeter movie camera and a high-speed rotating camera with film mounted on a rotating 3,600 rpm 12-inch drum which rotates past a fixed lens.

Tests Using Actual System-Recovery Voltage

Standard rod gaps were used in all studies reported here. The test-circuit insulation levels are adequate for studying gap spacings up to about 15 inches. Previous data on lightning surge currents[8] had been obtained at gap spacings of 6 and 11 inches. Most of the data discussed here were obtained at the same spacings to correlate with those tests. In addition 3-inch gaps were studied.

When using the actual system-recovery voltage of the circuit supplying the fault current, the logical procedure is to vary one of several possible parameters until critical reignition is reached. A point on a dielectric-recovery curve then can be obtained by the crest magnitude and time to crest of the system-recovery voltage when the arc just fails to restrike. The parameters which can be varied are the time constant of the circuit to control the rate of rise of the system-recovery voltage, the applied circuit voltage to control the magnitude of the recovery voltage, the magnitude of the fault cur-

rent, and the gap spacing. Unfortunately, it is difficult to vary any one of the above parameters without causing appreciable changes in one or more of the others. Variation of circuit voltage or system natural frequency at a fixed fault current produces a very slow test procedure since it requires an accurate readjustment of the current-limiting reactor. The best test procedure found was to set the circuit voltage, natural system frequency, and limiting reactor and then vary the gap spacing until the critical reignition condition is reached.

With gaps of the order of three to six inches, it was found that the circuit voltage had to be reduced to the order of 1,000 volts rms, or less, before arc extinction would occur naturally with fault currents of practical magnitudes. This was true with system natural frequencies as low as 300 cycles per second. Even then the currents were below 50 amperes. Therefore this phase of the study necessarily was confined to currents of this magnitude or less. Under these conditions the arc drop was appreciable and, as is to be expected, accurate reproduction of test conditions was difficult. It was found in all cases that if the arc extinguished itself naturally it did so within the first half-cycle or at the first current zero. However, for any two faults with identical settings of the controllable parameters the magnitude and duration of fault current from its start to the first current zero varied considerably. This erratic characteristic therefore requires so many tests to get a mean critical condition that enough points for even a portion of a dielectric-recovery curve can not be obtained in a short enough time so that the effects of variations in atmospheric conditions can be eliminated or studied.

Table I lists 76 sets of critical reignition test runs that were made. In the tabulation are given the applied voltage-crest fault current, per cent of one-half cycle of the fault current, crest magnitude, and time to crest of the system-recovery voltage. The current data apply to the actual oscillograms from which the recovery voltage point was scaled at the test shot on which the circuit just recovered. A typical oscillogram from which these data were obtained is shown in Figure 8. As shown in Table I, the crest current ranges from 7 to 52 amperes and the time to current zero from 18 per cent to 100 per cent of a half-cycle. Various analyses of the data were attempted, such as segregating into groups of limited current variation, but the spread in the points as plotted on dielectric-recovery curves completely masks any effects of variation in the fault current. The only logical segregation found is with regard to gap spacing. In Figure 9 are plotted all records segregated into two groups of gap spacings. These data will be discussed in more detail later.

Tests Using Two Surge Generators

With the ignitron circuit and sufficiently high circuit voltages so that arc drop is not a factor, accurate control of the magnitude and duration of the fault current is obtained. Individual tests can be made at the charging rate of the surge generator or 1-minute intervals. Thus the study of the effects of the controlling factors becomes practicable since the circuit test conditions can be accurately

duplicated and many test points obtained during essentially constant atmospheric conditions.

The method of testing the gap, at a given time interval following the end of the fault current, is to raise the voltage applied by the Number 2 generator until breakdowns occur. Then oscillograms are obtained over a sufficient voltage range to produce a volt-time or time-lag curve. It is not considered necessary to use a standard $1^1/_2$ by 40-microsecond wave. The volt-time curves under the conditions of a predischarge are much flatter than with no predischarge and unaffected by large variations in the tail of the test waves. This had been observed previously for the lightning surge studies.[8] Typical volt-time curves both with and without a predischarge are shown in Figure 10. Two things of interest are illustrated by this figure. One is the more random nature of the data when the medium is recovering from a fault. The other is the fact that although the volt-time curves plotted through points obtained in this way have less turn-up than for gaps without a predischarge, the breakdown can occur at much longer time lags. Further, it was found that for a region of time intervals (that increase with magnitude of the fault current) breakdown can occur at a relatively slow rate. This is illustrated by the oscillograms of Figure 11. This same phenomena had been observed when studying gaps recovering from high-current short-duration surge currents.[5] There, however, it was found only for time intervals less than about 100 or 200 microseconds or when the gap is still carrying small currents. In the case of one or two half-cycles of power-frequency fault current this region extends to about 40,000 microseconds for 100-ampere faults and to about 70,000 microseconds for currents as high as 700 amperes. The percentage of such slow breakdown records decreases at the longer intervals. However, even though all breakdowns are at this slow rate there still exists a definite critical voltage below which breakdown will not occur. Because of this type of breakdown and the possibility of the media not supporting voltages below the apparent critical, it was considered desirable to use as long tail test waves as practicable. Surges with a time to half-value of about 80 microseconds were used for the data in all of the dielectric-recovery curves except the highest point on the 11-inch gap curve, Figure 14(B). As shown by Figure 11, partial breakdowns were also recorded at the shorter time delays after current zero.

High-Speed Camera Studies

Much valuable information has been obtained from the high-speed photographic studies, particularly from the records obtained with the 3,000-frame-per-second movie camera. Portions of one of the more interesting of these records are shown in Figure 12. The first group of frames shows the first 2,300 microseconds of the fault-current arc. The second group shows the luminous gases present in the arc 0.013 second after the start of the fault or 0.0043 second after the end of current flow. The third group shows the luminous gas in the arc just prior to the flashover produced by the Number 2 surge generator 0.041 second after the start of the fault or 0.0322 second after the end of the fault-current flow. In all cases photographed the luminous gases either moved out of the

Figure 11. Typical oscillograms showing slow breakdown characteristics obtained when number 2 generator voltage is applied at short time intervals

center of the gap toward the electrodes or the gases near the electrode remained luminous longer. As shown in the third group of records in Figure 12, there still remains a faint path of luminosity in the gap through which the second discharge occurred. In all recorded cases the period in which visible luminous gas remains in the central region of the gap corresponds to the maximum delay for which slow voltage breakdown is observed. The fourth group shows the second discharge, and the fifth, the luminosity which still persisted at one terminal after 0.12 second. Faint traces of luminous gas are visible in such a record as long as 0.15 to 0.17 second after the end of the fault current even though no second discharge is applied.

Detailed examination of such records shows that extensive motion in the arc path occurs even during the half-cycle of fault current. The arc develops, then expands radially (in, of course, a tortuous corkscrew path) with visible diameters of two or three inches. The luminous area shown in the frames reaches its maximum at the crest of the fault current and diminishes only slightly by the time

the fault current reaches zero. For half-cycle faults it is quite intense for three or four more half-cycles. However, it does not drift out or away from the general region of the gap in the period that it is photographically visible.

The record in Figure 12 is of particular interest since it shows that a large time interval was required for the second discharge to build up to maximum intensity. This corresponds to the slow rate of breakdown mentioned previously. The first frame of the fourth set shows initial streamers propagating from each electrode through the trail of luminous gas. The next frame shows the intense return streamer that completes the discharge. Of these two initial streamers the one passing through the gas of greatest luminosity is more intense itself. The time interval between these two frames is about 400 microseconds, but of course about 300 microseconds of time is lost by the shutter action and the first faint trace may have started just before the shutter closed. Thus the actual time of build-up can not be determined from such a record. Actually the longest times for breakdown to develop as recorded with the oscillograph were of the order of 30 or 40 microseconds. This was true even for very short time intervals between the end of the fault current and the application of the test voltage.

The photographic records showed that for time intervals above 70- or 80,000-microseconds, the second discharge de-

parts greatly from the path of visual luminosity. By this time the hot gases have disappeared in the central region of the gap and the second discharge takes a straight path between the electrodes.

Effect of Atmospheric Conditions

The tests reported here were performed with air under natural conditions and subject to normal variations. As significant changes occurred in the weather, test runs were repeated to determine the effect. In such cases the variations between mean critical breakdown values were of the same order of magnitude as the standard correction factors to be applied to air without a predischarge. Typical data of this type is shown in Figure 13. The principal results o' the grouping of the three runs is the correspondingly greater spread in the points. The application of the standard correction factor for varying atmospheric conditions to the test data brought the grouping closer together. In most of the data presented here, such correction factors amount to only three or four per cent at the most. Under these conditions they were applied to the data but probably have no significance. Only the two points shown in Figure 14(B) had larger correction factors.

Dielectric-Recovery Curves

Thirty-five or forty test points appear to be adequate for establishing a critical point on a dielectric-recovery curve. However, two to four such runs were made at each time interval in an attempt to establish accurately the dielectric-recovery curves presented here. Thus each point is the result of 70 to 150 actual tests. The data obtained for longer time intervals is plotted in Figure 14 for 3-, 6-, and 11-inch horizontal rod gaps. As shown, the bulk of the data has so far been obtained for one-half cycle of power current. Shorter duration arcs have not yet been studied in detail. It has been found that the rate of recovery is relatively insensitive to longer durations. Points obtained with one or two cycles of fault current are not appreciably different than those for one-half cycle.

Comparison of the three-inch and six-inch gap data in Figure 14 shows that not only is the strength of the three-inch gap proportionately higher at any time interval but its relative rate of recovery is more rapid. Examination of critical breakdown curves for rod gaps without a predischarge shows that the relative strength of a 3-inch gap is greater than a 6-inch gap whereas the curve becomes a straight line above six inches. This is due to the gap configuration and probably also explains the first of the above comparisons for the cases with predischarges. The second effect is probably due to electrode cooling. The greater conductivity of the electrodes can have an appreciable effect in cooling air adjacent to each electrode. For gaps of six inches or more this effect should not be appreciable as shown by the comparison between the 11-inch and 6-inch gap curves. These show quite similar rates of recovery and the 11-inch data have the same proportionality factor at all points. It thus appears evident that data obtained from gaps of these lengths can be extrapolated to larger gap spacings. These same considerations apply to data of Figure 9 for tests obtained using natural system recovery. Here gaps in the region of three inches have about twice the proportionate rate of recovery as 6-inch gaps. This is somewhat higher than the proportionate ratio observed in Figure 14.

The 6- and 11-inch gap data of Figure 14 show that for fault currents of 100 to 700 amperes, time intervals of 0.02 to 0.04 second are required for the insulation to recover to one-fourth of its original strength and 0.05 to 0.08 second to recover to one-half its original strength. This region corresponds to the normal range of ratios of original transmission-line insulation strength to normal applied voltage showing the time intervals required after the interruption of the fault before it is safe to reclose the circuit breakers.

Figure 15 shows the correlation (in the region of shorter time delays) between the two types of tests described here and data previously obtained[5] with high-magnitude short-duration fault currents representative of lightning surges. The very rapid recovery to lightning-surge currents is contrasted with the much slower recovery, even to power-frequency currents as low as 20 to 50 amperes. The relatively slow rates of recovery for 60-cycle fault currents make it appear unlikely that normal power-line insulation would recover after an appreciable fraction of a half-cycle of fault current flows unless after such long times that the arc has extended itself greatly by rising out of the central region of the gap. Assuming an average of 0.25 for the ratio of normal system voltage to normal insulation strength, one finds from the dielectric-recovery curves that even if the system transient or recovery voltage did not exceed normal voltage, its frequency would have to be less than 60 cycles to prevent its crossing the dielectric-recovery curve. For a system natural frequency of 1,000 cycles per second and assuming an overvoltage of 1.5 times normal, the ratio of normal applied voltage to normal insulation level would have to be of the order of 0.01 or less. However, as shown by the dielectric-recovery curves for short-duration surges, a good probability exists for recovery at a high-frequency current zero. This was discussed in reference 5.

Future Tests

Unfortunately this is a very complex subject and many more tests are required before some of the important conclusions can be reached on this subject. Data have to be obtained for fault-current durations between the range of the short-duration lightning surges and appreciable fractions of one-half cycle of power frequency. The effects of appreciable air velocities and of gap positions must be studied and similar data obtained for other media such as insulator strings and wood insulation. This, together with a fundamental study of the mechanism of recovery and breakdown during the second discharge through the weakened arc path, constitute the second phase of this project now in progress.

Discussion

O. Ackermann (Westinghouse Electric Corporation, East Pittsburgh, Pa.): Anybody who has worked on the recovery characteristics of arcs will agree fully with the authors that the subject is very complex and that it is difficult to perform significant tests, that is, tests from which any conclusions can be drawn beyond the immediate region within which they have been performed. In other words, extrapolation so far has been very risky. In order to fit isolated groups of data into a coherent pic-

Figure 1. Interrupting ability of rod gaps (5.5 to 11 inches) at low 100-per cent power-factor 60-cycle currents

A. Applying to both horizontal and vertical gaps: limit for clearing within four cycles
B. Applying to vertical gaps only: limit for clearing at all, sometimes after as much as 30 cycles
C. Limit of explored area; horizontal gaps clear anywhere within this range, sometimes taking up to 70 cycles
D. Average gradient for initial breakdown of rod gap

ture, a reliable core or outline is needed such as now is taking shape in the hands of the authors of this paper.

A few years ago the writer found it necessary to check into the clearing ability of the air gaps employed in series with expulsion-type arresters for transmission lines, the question being, what leakage current flowing over the outside of the tube or over an insulator supporting the tube can be interrupted by the series gap. Tests were made on rod gaps ranging from $5^1/_2$ to 11 inches, both in vertical and in horizontal position; the currents were limited to 500 milliamperes and less. The data were coordinated on the basis of kilovolts rms per inch of gap spacing; the results are shown in Figure 1 of the discussion. Horizontal and vertical gaps clear equally well in the current and voltage range where the clearing requires only a few cycles, that is, while the arc still is in the more or less direct line between the two electrodes. In the subsequent cycles some flaring out and lengthening occurs even in the vertical arc, but the process cannot go very far and the arc will not clear at all unless it can do so within the first 30 cycles. Horizontal arcs never failed to clear within the range of the performed tests, which is indicated by line *C* in Figure 1 of the discussion.

In all these tests the current was entirely resistance limited; therefore, after current zero, the voltage reappeared across the gap in the form of a symmetrical 60-cycle sine wave, starting from zero. In the critical clearing tests indicated by line *A* in Figure 1 of the discussion, the dielectric-recovery curve of the gap must have more or less followed that sine wave. To see how this fits into the picture presented by the authors in Figure 15 of the paper, we select the 5-kv 66-milliampere point of our line *A*, convert the voltage to that for an 11-inch gap, that is, 55 kv rms, 78-kv crest, and plot the corresponding sine wave in Figure 15. This is done in the Figure 2 of the discussion, and it appears that the new curve, although arrived at by an approximative method, fits fairly well into the general pic-

Figure 2. Comparison of dielectric-recovery characteristics of an 11-inch rod gap for different types of predischarge

ture and adds information on one of the numerous fringe areas to this extensive problem.

G. D. McCann, J. E. Conner, and H. M. Ellis: The authors were happy to receive the additional information provided by Mr. Ackermann's discussion and to see the agreement with data presented in the paper. As pointed out by Mr. Ackermann, the very great complexity of this subject makes it extremely risky to rely on a few isolated points for reliable information on dielectric recovery or try to extrapolate into unconfirmed regions.

It was for these reasons that so much effort has been devoted by the authors to the development of a reliable and sufficiently rapid dielectric-recovery testing technique that makes possible a comprehensive study of this subject.

Total and Incremental Losses in Power Transmission Networks

J. B. WARD
MEMBER AIEE

J. R. EATON
MEMBER AIEE

H. W. HALE
ASSOCIATE AIEE

THE FIRST development of a loss formula wherein total transmission losses are expressed in terms of source loadings was presented by E. E. George[1] in 1943. In a recent paper[2] a formula of this type was used to co-ordinate losses and station costs in obtaining optimum operating economy. An appendix in this latter paper describes a modification of George's original method, adapted to the use of the network analyzer for evaluating the constants. The present paper describes an extension or generalization of George's original formula, together with improved techniques of evaluating the constants by use of the analyzer. A simple relation which gives the incremental loss incurred in transferring a block of generation from one source to another is derived from the total loss formula.

The loss formula is derived by an application of the principle of superposition. Two basic approximations are involved. First, for a given total load each individual substation load is represented as a certain current which has a constant magnitude and fixed relative angular position with respect to other load currents, regardless of the manner in which the total generation is apportioned among the sources. Second, as the total system load varies the magnitude of each individual load current varies proportionately and maintains its fixed relative angular position with respect to other load currents. Suitable values of load currents may be obtained from a selected, typical, intermediate power-flow condition which is taken as the normal or reference condition.

The complete process of developing a loss formula for a system is explained through the medium of an example worked out for a sample system.

Determination of Loss Formula for a Sample System

The method of determining a loss formula is illustrated in detail on the sample system shown in Figure 1. This system is purely hypothetical and is relatively simple in order to minimize the space required to explain the calculations. However, the system is sufficiently representative and complete to serve as a guide for applying the method to larger systems.

Impedances are given in per cent on a 100 megavolt-ampere base. Off-nominal transformer ratios are indicated as per cent deviation from nominal ratio. Note that ratios in the two transformer banks supplying the 66-kv system are not the same, as frequently occurs in practice. In such instances, the difference in ratios is usually small or the loop impedances are large, resulting in small circulating current due to the residual turn ratio. The transformer ratios are retained at the values shown for subsequent tests.

Complete network analyzer readings for the operating condition chosen as the basis for deriving the formula constants are shown in Table I. It should be emphasized that the algebraic signs associated with the vector current readings in Table I have no significance except in relation to the analyzer plugging diagram

Table I. Normal Power Flow Condition

Points indicate calculated incremental losses from check studies

which is not shown. The important point is to maintain consistently throughout all tests the same circuit polarity. The vector reference used for these readings is the total source current (generators and tie-lines).

In addition to the normal power-flow study, a number of other operating conditions were established on the analyzer, readings taken, and losses calculated line by line to serve as checks on the formula results. Some of these conditions are summarized in Table II. These check studies were adjusted in the conventional manner, with loads maintained at scheduled values of real and reactive power.

The simplified form of the loss formula, as given by equation 7 in Appendix II, is derived for this sample system in the following paragraphs. An incremental loss formula for through transfer between the interconnection points at Stations (3) and (4) is derived from the total loss coefficients. The formula for total transmission loss is given in Appendix IV, together with the assumed values of constant source voltage and power factor. Comparison of the results yielded by this formula with the results of calculated losses in the check studies is shown in Figure 2. The check studies listed in Table II are noted on the diagram.

Figure 2. Comparison of calculated and formula results

Figure 3 gives the incremental loss formula, the corresponding parabolic curve, and several points calculated from the check studies.

Determination of Separate Line Flows

Certain analyzer tests are required in addition to the normal base power-flow condition. These additional tests are simple to perform, since they are all made with load and capacitor circuits opened. Their purpose is to determine what the current in each line would be if the normal-flow load and capacitor currents were supplied by one source at a time. These line currents are derived indirectly by an application of the principle of superposition. This expedient is taken to avoid the difficult task of reproducing these separate-source line flows directly on the analyzer.

The first step is to select one source, preferably a centrally located major source, as the key or reference point. In the present example, the low-voltage bus at Station (1) is chosen for this purpose. With load and capacitor circuits opened on the analyzer setup, and with transformer taps on normal settings, the following operations are performed:

1. Connect the selected key bus (Station (1)) to neutral through a metered jumper circuit which is polarized in the same way as Station (1) generator circuit. Open the generator at Station (1).

2. Connect a high-impedance buffer circuit in series with each of the other sources. Energize these sources and adjust them so that the vector current in each, with respect to a common reference, is the same as the corresponding vector current in the normal-flow condition, Table I. It is desirable to

Table II. Source Loadings and Calculated Losses from Check Studies

* Column A: Readings from analyzer test with generator (1) bus grounded, all loads and capacitors opened, and normal-flow current impressed at (2), (3), and (4). All readings taken with respect to a common reference.

** Column B: Derived line flow giving the current distribution if source (1) alone supplied normal load currents. To obtain the values in this column, subtract the readings of column A from corresponding normal-flow measured values.

† Current in metered jumper used to ground bus (1). This metering circuit is polarized the same as the generator circuit it replaces.

†† This value, 2.397, is the value of C_1 used in evaluating the loss formula constants.

have the buffer impedances as large as possible in order to make the adjustment of each source current nearly independent of the others. Read and record all line currents as shown in Table III, column A. In the event that full value would produce currents in excess of circuit or instrument ratings, all of the impressed source currents may be reduced to one-half or one-quarter value, and then the resulting line currents corrected to full value.

In the presence of off-nominal turn ratios in the network, the current in the grounding circuit at the reference bus may differ from the sum of impressed currents in other sources. Note that such a difference appears in the data of Table III, column A.

Column B of Table III is obtained by subtracting values in column A from the corresponding currents in Table I. All source currents except (1), the key or reference bus, vanish, and the line currents are the correct values for Station (1) alone supplying normal load currents. This follows from the fact that since the two sets of line currents, namely normal flow and those in column A, separately satisfy Kirchhoff's laws in the network, the currents resulting from their superposition must also satisfy Kirchhoff's laws. As a result of the superposition, all source currents vanish except at source (1). The line flow of column A contributes nothing to loads, since it was taken with loads off. Hence, the resulting combined line currents represent the condition of source (1) alone supplying normal load currents.

3. Next, it is desired to determine the line currents when source (2) alone is supplying normal load currents. To this end, a simple additional test is made. Open all sources except number (2), leaving loads and capacitors off and generator (1) bus grounded. Energize source (2) and adjust it so that the current in the grounding jumper at bus (1) is equal and opposite to the source (1) current appearing in column B, Table III; that is, the source (1) current when this source alone supplies normal load currents. Again it may be necessary to limit the current to a lower value. Read and record the line currents as shown in column AA, Table IV. Column BB of Table IV is obtained by adding column AA to column B of Table III. All source currents except (2) vanish, and the resulting line currents are the values for station (2) alone supplying normal load currents.

4. Repeat step 3 for each other source.

In a larger system it may be more convenient to record current readings directly on a 1-line diagram rather than in tabular form.

The combination of different sets of line currents could also be carried out directly on these diagrams.

Calculation of the Constants

The single-source line flows as obtained from the previously described analyzer tests furnish the necessary information for calculating the formula constants. The details of subsequent calculations will depend, to some extent, on what simplifying assumptions are made. In the present example, the simplified formula, in the form of equation 7 in Appendix II, will be derived.

The bulk of the required calculations is involved in evaluating the K and H constants. Sample calculations for sources (1) and (2) are shown in Table V. Column 1 lists identification of the lines and transformers and column 2 the corresponding per cent resistance. The scalar magnitudes of line currents for source (1) alone energized, as obtained from Table III, column B, are entered in column 3. The square of each line current multiplied by the corresponding per cent resistance is entered in column 4. The sum of all values in column 4 is used to obtain the value of K_{11}, as shown in the sample calculation at the bottom of Table V.

Next, cross-products of the real components of single-source line flows associated with sources (1) and (2) are multiplied by corresponding line resistances, as indicated in column 5. Similar cross products of the quadrature components are shown in column 6. The totals of columns 5 and 6 produce the K_{12} constant as indicated at the bottom of Table V.

The operations involved in obtaining the elements of columns 7 and 8 are indicated in literal form in the column

Table IV. Determination of Line Currents with Station (2) Alone Supplying Normal Load Currents

Total			15.645	−5.463	0.137	−0.507	0.029

Note: From Table III, $C_1=2.397$; From Table IV, $C_2=2.140$

$$* K_{11}=\frac{10}{C_1^2D}\sum i_{k1}^2R_k=\frac{10}{(2.397)^2\times 100}\times 15.645=0.273$$

$$* K_{12}=\frac{20}{C_1C_2D}\sum(a_{k1}a_{k2}R_k+b_{k1}b_{k2}R_k)=\frac{20}{2.397\times 2.140\times 100}(-5.463+0.137)=-0.208$$

$$** H_{11}=\frac{20}{C_1C_2D}\sum(a_{k1}b_{k2}R_k-b_{k1}a_{k2}R_k)=\frac{20}{2.397\times 2.140\times 100}(-0.507-0.029)=-0.021$$

headings. The totals of these two columns yield the H_{12} constant.

The complete set of K and H constants requires computations of the type indicated in column 4 for each source and in columns 5–8 for each pair of sources. The H_{12} constant is included in Table V to illustrate the computations; however, the H constants were neglected in obtaining the B constants of Appendix IV. Note also that the summation of column 6 contributes very little to the value of K_{12}. With fairly uniform load-power factor and line resistance-to-reactance ratios, the quadrature component of single-source flows might be neglected altogether. This would reduce the computations to a single column for each source and each pair of sources.

In the present example additional assumptions are made to the effect that source bus angles may be neglected and that source voltages and power factors remain constant at values listed in Appendix IV. A sample calculation of B_{12} is given here (equation 10, Appendix II)

$$B_{12}=\frac{1}{2V_1V_2}(1+r_1r_2)K_{12}=\frac{1}{2\times 1.05\times 1.05}\times(1+0.49\times 0.23)(-0.208)=-0.105$$

Conclusions

The complete formula developed herein (see equation 5, Appendix II) expresses the total system loss in terms of four variables for each source, namely, P, Q, V, and ϕ. This form usually will be too complicated for practical applications. However, it is useful for evaluating the effects of simplifying assumptions. The assumption of constant values for ϕ is necessary from a practical viewpoint, since relative angular displacements of source bus voltages are not obtainable from system log sheets, nor are they easily estimated in complex networks. It is felt that the assumptions employed in the numerical example will yield satisfactory results on most systems. A few check studies should always be made to furnish a check on calculations as well as the assumptions.

A basic assumption of the method is that during the normal cycle of system load variation all loads vary in proportion. If a major load does not conform with the pattern of variation followed by the rest of the system, this load may be treated as a negative source and introduced as an additional variable in the formula. In the event that many loads vary in a nonuniform manner, it may be necessary to develop two or three sets of constants in order to cover the entire daily load cycle.

In choosing the source points which will appear as variables in the loss formula, it is desirable to hold the total number to a minimum. Generators within a station can usually be combined, and small plants may sometimes be eliminated by combining with local loads. It may be feasible to combine separate plants which are close together electrically.

The parabolic incremental loss formula may be useful for certain applications. Considering the difficulty of analyzing incremental losses, this formula is capable of showing quite well the pattern of variation in losses resulting from power interchange between pairs of stations or interconnection points. This formula, for any pair of sources, can also be derived from simple analyzer tests without the necessity of obtaining the total-loss formula for the system.

Appendix I. Nomenclature

$P_1, P_2, \ldots P_s$ = real power loading, in megawatts, of sources (generating stations or interconnection points); assumed positive when power is supplied to the system.

$Q_1, Q_2, \ldots Q_s$ = reactive power loading of sources, in megavolt-amperes; assumed positive when lagging reactive power is supplied to the system.

$V_1, V_2, \ldots V_s$ = magnitude of source terminal voltages, in per unit.

$\phi_{mn}=\phi_m-\phi_n$ = phase angle difference between terminal voltages of sources m and n.

$r_n=Q_n/P_n$ = tangent of power factor angle.

P_L = total I^2R transmission loss in kilowatts.

ΔP_L = incremental transmission loss in kilowatts.

p_{kj} = block of generation, in megawatts, transferred from source j to source k, that is, P_j is decreased and P_k is increased by p_{kj}.

K_{mn}, H_{mn} = constants of the complete loss formula.

B_{mn} = constants of the simplified form of loss formula.

A_1 and A_2 = constants of the incremental loss formula.

D = power base, in megavolt-amperes. Currents and impedances are expressed in per cent or per unit on this base.

R_k = resistance of line k, in per cent on base D.

G = magnitude of the summation of all vector source currents in reference power flow condition. Expressed in per unit on base D.

$i_k=a_k+jb_k$ = current in line k, in per unit on base D, under any general operating condition.

$g_n=c_n-jd_n$ = current in source n under any general operating condition, in per unit on base D. Vector reference is the same as that used for source voltage angles ϕ_n.

C_n = magnitude of source n current, in per unit, when this source alone supplies normal-flow load currents. In the absence of off-nominal transformer tap settings G and C_n are equal.

$i_{kn}=a_{kn}+jb_{kn}$ = per unit current in line k when source n alone supplies the normal-flow load currents. Vector reference is the corresponding source n current, C_n.

Appendix II. Derivation of Loss Formula

Consider a special type of network, as shown in Figure 4, in which each individual load current is a constant fraction of the total load current and maintains a fixed relative phase position with respect to other load currents. The total load current may be apportioned in any way among the s sources. Autotransformers may appear in

Figure 4. Idealized network

the network, and in their presence the total load current will not necessarily be equal to the total source current. It is assumed that the network connections remain intact.

The following development is exact for the network of Figure 4. With certain approximations and in the range of normal operation, the single-phase diagram of a power system may be visualized as a network of this nature.

Let $i_{kn} = a_{kn} + jb_{kn}$ denote the per-unit current in line k when source n alone supplies a specified set of load currents. The vector reference of i_{kn} is taken as the source n current C_n.

Let $g_1, g_2, \ldots, g_s$ represent per-unit source currents resulting from some arbitrary apportionment of the total load among the s sources of the system. These source currents are referred to an arbitrary, common vector reference. The resulting current in line k may be obtained by superposition

$$\begin{aligned} i_k = i_{k1}(g_1/C_1) + i_{k2}(g_2/C_2) + \ldots + \\ i_{ks}(g_s/C_s) = (a_{k1}+jb_{k1})(c_1-jd_1)/C_1 + \\ (a_{k2}+jb_{k2})(c_2-jd_2)/C_2 + \ldots + \\ (a_{ks}+jb_{ks})(c_s-jd_s)/C_s \end{aligned} \quad (1)$$

Expand the products in equation 1, and separate the real and imaginary parts. The square of the magnitude of i_k is obtained by taking the sum of the squares of these real and imaginary parts. Upon collecting terms in the resulting expression, we obtain

$$\begin{aligned} i_k^2 = a_k^2 + b_k^2 = (c_1^2+d_1^2)(a_{k1}^2+b_{k1}^2)/C_1^2 + \\ (c_2^2+d_2^2)(a_{k2}^2+b_{k2}^2)/C_2^2 + \ldots + \\ (c_s^2+d_s^2)(a_{ks}^2+b_{ks}^2)/C_s^2 + \\ 2(c_1c_2+d_1d_2)(a_{k1}a_{k2}+b_{k1}b_{k2})/C_1C_2 + \\ \ldots + (\text{similar terms for each pair of sources}) + 2(c_1d_2-d_1c_2)(a_{k1}b_{k2} - \\ b_{k1}a_{k2})/C_1C_2 + \ldots + (\text{similar terms for each pair of sources}) \end{aligned} \quad (2)$$

The loss in kilowatts is obtained by multiplying the square of the current in line k by $10DR_k$, and total loss is the sum of the losses in the individual lines; that is

$$P_L = 10D\sum_k i_k^2 R_k \quad (3)$$

Source currents may be expressed in terms of real and reactive power loadings and terminal voltages. If the source terminal voltages (vector expressions) are given with the same reference as source currents, then

$$\begin{aligned} c_n &= (P_n \cos\phi_n + Q_n \sin\phi_n)/V_nD \\ d_n &= (Q_n \cos\phi_n - P_n \sin\phi_n)/V_nD \end{aligned} \quad (4)$$

where positive value of Q_n denotes lagging reactive power supplied to the system.

Upon substituting expressions 4 for c and d in equation 2, the total power loss in kilowatts, equation 3, may be written

$$\begin{aligned} P_L = \frac{P_1^2+Q_1^2}{V_1^2}K_{11} + \frac{P_2^2+Q_2^2}{V_2^2}K_{22} + \ldots + \\ \frac{P_s^2+Q_s^2}{V_s^2}K_{ss} + \frac{P_1P_2+Q_1Q_2}{V_1V_2}\times \\ [K_{12}\cos\phi_{12} - H_{12}\sin\phi_{12}] + \ldots + \\ \frac{P_{s-1}P_s+Q_{s-1}Q_s}{V_{s-1}V_s}[K_{(s-1)s}\times \\ \cos\phi_{(s-1)s} - H_{(s-1)s}\sin\phi_{(s-1)s}] + \\ \frac{P_1Q_2-Q_1P_2}{V_1V_2}[H_{12}\cos\phi_{12} - K_{12}\sin\phi_{12}] + \\ \ldots + \frac{P_{s-1}Q_s-Q_{s-1}P_s}{V_{s-1}V_s}\times \\ [H_{(s-1)s}\cos\phi_{(s-1)s} - K_{(s-1)s}\times \\ \sin\phi_{(s-1)s}] \end{aligned} \quad (5)$$

where

$\phi_{12} = \phi_1 - \phi_2$; $\phi_{13} = \phi_1 - \phi_3$; and so forth

$$K_{nn} = \frac{10}{C_n^2 D}\sum_k (a_{kn}^2 + b_{kn}^2)R_k$$

$$K_{mn} = \frac{20}{C_mC_nD}\sum_k (a_{km}a_{kn} + b_{km}b_{kn})R_k$$

$$H_{mn} = \frac{20}{C_mC_nD}\sum_k (a_{km}b_{kn} - b_{km}a_{kn})R_k \quad (6)$$

The summations in equations 6 are taken over all lines in the network.

Equation 5 gives the total loss in the network as a function of four variables for each source, namely: P, Q, V, and ϕ. The number of additive terms in equation 5 is equal to the square of the number of sources. This expression is rigorous for the hypothetical network of Figure 4. It holds true approximately for power networks in so far as their characteristics conform approximately with those of the idealized network of Figure 4. For adaptation to practical power-system problems, the following simplifications are suggested to obtain a more usable loss formula. The effects of these assumptions may be analyzed for a given system, and a reasonable combination chosen to fit the requirements.

1. Assume the source bus voltage angles remain fixed at the value attained in some typical, intermediate operating condition. Then each quantity in brackets in equation 5 may be treated as a single constant.

2. If the magnitudes of source bus voltages remain essentially constant, then the voltages in equation 5 may be absorbed in the constants.

3. The jb_{kn} components of separate-source line flows will be negligibly small when load power factors are fairly uniform, line resistance-to-reactance ratios are essentially uniform, and loops containing transformers close with regard to turn ratio. This means that the H constants may be neglected and scalar current distribution used for i_{kn}.

4. A convenient form of loss formula is obtained if in addition to items 1 and 2 it is assumed that each source operates at a constant power factor, thus making the ratios Q_n/P_n constant.

$$\begin{aligned} P_L = P_1^2B_{11} + P_2^2B_{22} + \ldots + P_s^2B_{ss} + \\ 2P_1P_2B_{12} + 2P_1P_3B_{13} + \ldots + \\ 2P_{s-1}P_sB_{(s-1)s} \end{aligned} \quad (7)$$

$$P_L = \sum_{m=1}^{s}\sum_{n=1}^{s} P_mP_nB_{mn} \quad (8)$$

where

$$B_{nn} = \frac{(1+r_n^2)}{V_n^2}K_{nn} \quad (9)$$

$$\begin{aligned} B_{mn} = B_{nm} = \frac{1}{2V_nV_m}\{[(1+r_mr_n)\times \\ \cos\phi_{mn} - (r_n - r_m)\sin\phi_{mn}]K_{mn} + \\ [(r_n - r_m)\cos\phi_{mn} + (1+r_nr_m)\times \\ \sin\phi_{mn}]H_{mn}\} \end{aligned} \quad (10)$$

$r_n = Q_n/P_n$

The data calculated from these equations is shown in Appendix IV.

Appendix III. Differential and Incremental Losses

The form of loss formula given in equation 7 or 8 leads to useful relations for an approximate analysis of incremental losses.

Assume that a very small (differential) increase in total load is imposed on the system and that this increase is supplied by source n. The change in total loss is obtained by differentiating equation 7, or 8

$$\begin{aligned} dP_L = \frac{\partial P_L}{\partial P_n}dP_n = [2P_1B_{1n} + 2P_2B_{2n} + \ldots + \\ 2P_nB_{nn} + \ldots + 2P_sB_{sn}]dP_n \\ = \left[2\sum_{j=1}^{s} P_jB_{jn}\right]dP_n \end{aligned} \quad (11)$$

Equation 11 is approximate for finite increments. For an incremental increase in loads, supplied by source n, the change in total loss is obtained by substituting the increased loading of source n, $(P_n + \Delta P_n)$, in equation 7 to obtain a new loss, P_L'. Then

$$\Delta P_L = P_L' - P_L = (\Delta P_n)^2B_{nn} + \left[2\sum_{j=1}^{s} P_jB_{jn}\right]\Delta P_n \quad (12)$$

The first term of equation 12, $(\Delta P)^2B_{nn}$, is an additive correction to equation 11 for finite increments. This correction may be interpreted as the loss which would be incurred if source n alone supplied the system with loads equal to the increment increase only.

It is frequently of interest to investigate the change in loss caused by shifting a block of generation from one source to another, with loads and other sources held constant. Let P_n be increased by increment p_{nm} megawatts, and at the same time let P_m be decreased by the same amount. Neglecting the effects of the incremental loss in so far as it modifies the total generation, the following relation is obtained for the incremental loss. In equation 7 substitute $(P_n + P_{nm})$ for P_n and $(P_m - p_{nm})$ for P_m to obtain the new loss, P_L'. The increase in loss due to the shift of generation is

$$P_L = P_L' - P_L = A_1 p_{nm}^2 + A_2 p_{nm} \quad (13)$$

where

$$A_1 = B_{nn} + B_{mm} - 2B_{nm}$$

$$A_2 = 2\sum_{j=1}^{s} P_j (B_{nj} - B_{mj}) \quad (14)$$

P_j is the initial loading of source j.

The second term in equation 13 may be interpreted as the total differential of equation 7 with P_n and P_m as variables, and the first term is a correction for finite increments. The first term in equation 13 is the loss incurred in sending P_{nm} megawatts (at normal voltage) from n to m over the unloaded transmission network. This interpretation neglects, as a second-order effect, the appearance of the incremental loss in the source loadings of the system.

Appendix IV. B Constants

A complete set of the B constants for the simplified loss formula have been calculated by the use of equation 10 in Appendix II. The values calculated are as follows:

$B_{11} = 0.306$	$B_{13} = 0.138$
$B_{22} = 0.667$	$B_{24} = -0.006$
$B_{33} = 0.229$	$B_{34} = -0.110$
$B_{44} = 0.362$	$B_{23} = 0.166$
$B_{12} = -0.103$	$B_{14} = -0.036$

Inserting these values in equation 7 of Appendix II, the loss formula becomes

$$P_L(\text{kw}) = 0.306P_1^2 + 0.667P_2^2 + 0.229P_3^2 + 0.362P_4^2 - 0.210P_1P_2 + 0.276P_1P_3 - 0.012P_1P_4 - 0.220P_2P_3 + 0.332P_2P_4 - 0.072P_3P_4$$

In computing the B constants, the H constants and the voltage angles ϕ were neglected. Assumed values of constant bus voltage and source power factor are as follows:

Source	V, Per unit	r
1	1.05	0.49
2	1.05	0.23
3	1.00	0
4	1.00	0

The quantity r equals Q/P or the tangent of the power-factor angle.

Discussion

W. R. Brownlee (Commonwealth Services, Inc., Jackson, Mich.): The simplifications developed by the authors for dealing with incremental transmission losses are of material value, especially the not too obvious omission of changes in losses due to changes in reactive kilovalt-ampere flows. While it is true that an incremental flow of kilowatts will actually result in a counter flow (incremental) of reactive kilovolt-amperes, the changes in losses due to the reactive kilovolt-ampere flow difference will be partly compensating. This is based on maintaining approximately constant voltages at generating plants, and departure from this assumption would cause greater changes in indicated losses than the omission reactive kilovolt-amperes from the loss formula.

The need for a thorough understanding of incremental loss calculations is highlighted by the difficulties of securing a check based on actual system readings. Most systems provide hourly readings of generator output, but in some instances the corresponding hourly readings on the low-voltage busses of transmission substations are not available. When these are available, a reasonable indication of total transmission losses might be obtained, but a check of incremental losses would be quite difficult. On the other hand, a high degree of accuracy in loss calculations may not be justified because of changes in syste .l load distribution and voltage differences.

Still further simplification is highly desirable in planning generating-unit additions and even for the more usual operating engineering analyses. In this simplified procedure, a direct comparison is required between two generating plants. The complete system with its many loads and generating stations then may be reduced to an equivalent load and generation at each of these two points, with an equivalent single-line impedance joining them. Since the fuel differences are in per cent, the incremental losses may best be expressed as a per cent of the incremental or transferred power. If the equation given in Figure 3 of the paper is divided by the incremental power, an expression for incremental losses in terms of per cent of the transfer power is secured, this formula being a constant times the transferred power plus another constant. The first term is a linear function of the transferred power times the equivalent line resistance, expressed in per cent on a base, divided by the system base. The second, or constant, term is secured by multiplying the initial equivalent power flow by the per cent equivalent line resistance and dividing by the system base.

L. K. Kirchmayer (General Electric Company, Schenectady, N. Y.): The authors have presented a very good exposition of their method of calculating total and incremental losses stating many of their simplifying assumptions. The method of superposition proposed in their paper avoids a number of the difficulties involved in obtaining the network analyzer data by previous methods in which the output of a given source, with the remaining sources open circuited, is adjusted to a value resulting in approximately 100-per cent current.

A study of the results obtained by making the various simplifications in the calculations proposed by the authors has been made for a 4-generator system. The results indicate that the accuracy obtained is not appreciably affected by the following simplifications which were suggested by the authors:

1. Neglecting the effect of ϕ_{mn} and the H_{mn} terms in the calculation of the power loss coefficients B_{mn}.

2. Neglecting $\sum_k b_{km} b_{kn} R_k$ in the calculation of K_{mn}.

In the authors' discussion of their method it appears that all shunt capacitors, including those representing line charging, are treated in a manner similar to the loads. Is it to be inferred that the assumption has been made that as the total system load varies, the magnitude of the line-charging currents is also considered to vary proportionally?

H. B. Smith (Niagara Hudson Power System, Buffalo, N. Y.): The authors have presented a very interesting paper. I think all will agree with the statement under the section on Conclusions that equation 5 is too complicated for practical applications. However, the authors are to be thanked for developing and presenting this equation as a basis for simplifying assumptions.

Referring to equation 2 of the paper and the simplifying assumptions of Appendix II, I think it is worth while to point out that if all the $j\delta_{kn}$ components are negligible (assuming uniform load power factors, uniform ratios of r/x in the lines, no transformers in the network), then i_{kn} can be obtained by means of a d-c board. Furthermore, if C_n is kept equal to 1.0 per unit in each set of board readings, then all C_n^2 and $C_n\ C_m$ factors disappear in equation 2. In the case of the Niagara Hudson 115-kv transmission system, the foregoing assumptions are easily justified and therefore a d-c board is satisfactory for obtaining data for a loss formula. As I see it, the general form of equation 2 and the equations for determining the constants for the simplified loss formula (equation 7) then become

$$i_k^2 = a_k^2 + b_k^2 = (c_1^2 + d_1^2)a_{k1}^2 + (c_2^2 + d_2^2)a_{k2}^2 + \ldots + (c_s^2 + d_s^2) \times a_{ks}^2 + 2(c_1c_2 + d_1d_2)a_{k1}a_{k2} + \ldots$$

$$K_{nn} = \frac{10}{D}\sum_K a_{kn}^2 R_k$$

$$K_{mn} = \frac{20}{D}\sum_K a_{km}a_{kn}R_k$$

$$B_{nn} = \left(\frac{1 + r_n^2}{V_n}\right)K_{nn}$$

$$B_{mn} = \frac{1}{2V_nV_m} \times [(1 + r_mr_n)\cos\phi_{mn} - (r_n - r_m)\sin\phi_{mn}]K_{mn}$$

E. E. George (Ebasco Services, Inc., New York, N. Y.): This paper is of extreme interest because it removes one of the major difficulties in making accurate loss formulas on extended transmission systems, namely, that of maintaining proper load currents at substations remote from the single source of generation required in previous methods of determining a transmission-loss formula by the principle of superposition.

Although no opportunity to use this new method has arisen in our organization, an

effort will be made to try it out in the near future. The basic idea seems fundamentally sound and practical and may have application in connection with another approach to the calculation of transmission-loss formulas which is now engaging the attention both of the authors and of the discusser.

The assumptions required to be made are not particularly restrictive when one is studying good operating conditions on a system, either from the standpoint of low transmission loss or low delivered cost of power, because in such cases the angles between generating plants will never be very large.

There is still one moderate disadvantage in making transmission loss formulas by the superposition method. This disadvantage is the large amount of calculation, after the board work is completed, in making the coefficients in the loss formula. While this is simple algebra and arithmetic, it becomes very tedious in the case of systems having many generating plants. The work varies as the cube (or a higher power) of the number of generating plants. Any comments by the authors on possibilities of reducing this work would be welcome.

The authors are to be commended on the particularly clear and concise manner in which the paper was presented.

J. B. Ward, J. R. Eaton, and **H. W. Hale:** The authors wish to thank the discussers for their interest in the paper and for their comments and suggestions.

In answer to Mr. Kirchmayer's question regarding line charging, the method of the paper assumes that line-charging currents vary in the same manner as load currents. This is obviously not the correct representation for an essentially constant-voltage system; however, no other satisfactory method of treating line charging separately has occurred to the authors.

The large amount of calculation required, as pointed out by Mr. George, is very imposing when the method is applied to a widespread system. The time and amount of work required to make the calculations of constants (equation 6) may be appreciably reduced by proper subdivision of the several steps in the procedure. Furthermore, certain sums of products may be evaluated directly by analyzer measurements.

A Voltage Gradient Meter

R. L. TREMAINE
ASSOCIATE AIEE

R. C. CHEEK
MEMBER AIEE

EARLY in the studies now in progress on the Tidd 500-kv test lines at Brilliant, Ohio, it was thought that the voltage gradient at the earth's surface might have an important effect on corona and radio influence.[1] Since the phase conductors on a grounded neutral transmission system are grounded for d-c potentials through the transformers, the earth's gradient cannot cause a change in the potential of the conductors. However, it does induce a static charge on the conductors of such polarity and magnitude as to exactly nullify the potential which would exist in space if the conductors were not present. The presence of this induced static charge establishes a gradient on the surface of the conductors which theoretically is superimposed upon the gradient produced by the applied a-c voltage and therefore may alter the corona and radio influence performance of the line.

It was decided to include in the Tidd 500-kv test program studies of the effect of the earth's gradient. No gradient meter satisfactory for use on this project was available, so it was necessary to undertake the design and construction of a suitable instrument. The resulting device has a number of features which have not been available in any such instrument described previously in the literature and it is believed that a description of this instrument will be of value to other investigators.

This paper is devoted exclusively to the design and construction of the gradient meter itself. The studies of the effect of the earth's voltage gradient on corona and radio influence have not yet been completed, and the results will be reported at a later date.

Methods of Measuring Ground Gradients

Voltage gradient has been measured with a variety of methods. Generally speaking they fall into two classes. The more common type has a carefully insulated member which assumes the potential in space at which it is located, and its voltage with respect to ground is measured, usually with an electrometer. The insulated member may be a long wire parallel to the ground,[2,3] a Kelvin water dropper,[3] or some device employing a "collector." This may be a glowing fuse, or a radioactive element such as ionium, radio-thorium or polonium, the latter being more common. The action of the collector is to reduce the time required for the insulated member to assume the potential in space. The insulation requirements in this type of gradient meter are extremely severe, making the instrument sensitive to contamination. Such an instrument requires considerable attention.

The other common type of voltage gradient meter has provision for alternately exposing and shielding a grounded member from the earth's field. The change in the charge is a measure of the voltage gradient. In the earliest types the grounded member was a plate mounted level with earth or a sphere mounted on a hinged rod so that it could be raised or lowered.[4] The change in the charge was measured with a capillary electrometer. An improvement on this method is the so-called generator-type gradient meter which has a continuously rotating member.[5,6] The instrument described in this paper is of this type.

Extremely high voltage gradients may be measured by determining the current in the discharge from a sharp point.[7]

Design Considerations of the Gradient Meter

It was felt that a gradient meter suitable for use in the Tidd studies would have to meet the following specifications:

NECESSARY FEATURES

1. It must be suitable for use as either a graphic or indicating instrument.
2. It must indicate the polarity of the field.
3. It must cover a wide range on a single scale.
4. It must have sufficient scales so that fields of any magnitude likely to be encountered could be measured.
5. It must be insensitive to the a-c gradient from the test line which may be several times the d-c gradient.
6. It must be able to operate continuously in all weather.
7. It must have stable calibration.
8. It must be able to operate on 115 ± 10 volts alternating current.

DESIRABLE FEATURES

9. The ability to measure electric fields accurately without being partially buried.
10. Low insulation requirements.
11. Minimum distortion of the electric fields in the vicinity of the detection element.
12. Simple mechanical design.

The above requirements indicated thet a generator-type instrument should be designed.

Requirement number 5 is peculiar to this application, as the instrument is used in the vicinity of the Tidd experimental transmission lines which are operated at voltages up to 500 kv.

Paper 50-98, recommended by the AIEE Instruments and Measurements and the Transmission and Distribution Committees and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted November 1, 1949; made available for printing December 2, 1949.

R. L. TREMAINE and R. C. CHEEK are both with the Westinghouse Electric Corporation, East Pittsburgh, Pa.

The authors wish to acknowledge the assistance of C. F. Wagner, S. B. Griscom, and H. T. Akers in the design of this instrument and to thank A. R. Jones and J. S. Kinney for their work in the actual construction and operation of this instrument. They also wish to acknowledge the co-operation of American Gas and Electric Service Corporation.

Figure 1 (left). Schematic diagram of electric voltage gradient meter

Figure 3 (above). Operation of gradient meter during one revolution of rotor

(a) and (b) show the voltage of the stator for positive and negative fields respectively, and (c) shows the action of the mechanical switch. X and S indicate that the rotor is exposing and shielding the stator from the earth's field respectively. A = amplifier, M = meters, R = resistor

Description of Instrument and Its Operation

The exposed components of the instrument are the detector plates (stator) mounted in the center of the ground plane, and the rotor, which alternately shields and exposes the stator to the earth's electric field. These parts are mounted above the water and dust tight steel cabinet which houses the amplifier, motor, synchronous switch, and recorder. Figure 1 is a schematic diagram. Figure 2 gives a plan view of the rotor and detector element (stator).

For simplicity the explanation of the operation of this instrument will be given as if the stator were solidly grounded, starting with the completely covered position. When the stator is covered, there is no voltage gradient at its upper surface and hence its charge is zero. As the stator is uncovered, it is exposed to the earth's electric field and hence a voltage gradient is present over an increasing portion of its surface. A current flows through the ground connection of such magnitude that the charge distribution in the stator is that which is dictated by the voltage gradient on its surface. By the time the stator is fully exposed, sufficient current has flown through the ground connection so that the charge on the plates is that determined by the gradient at the surface of the earth. Since the charge on any conducting body is a function of the gradient at its surface, the charge on the stator per unit area may be calculated, if the gradient is known, by the equation

$$F = 4\pi q \qquad (1)$$

where

F = statvolts per centimeter

q = statcoulombs per square centimeter

The detector plates have an area of 364.9 square centimeters. The rotor is turned at 900 rpm so the plates are uncovered in 0.01667 second. If a voltage gradient of 100 volts per meter is assumed, equation 1 may be used to show that the current which would flow through the ground connection is 0.001936 $\times 10^{-4}$ amperes.

This current is much too small to be measured directly, so the stator is actually grounded through a 4.7-megohm resistor, and the voltage appearing across this resistor is fed into a special amplifier. The voltage which appears on the stator in the presence of a field of 100 volts per meter is 0.00910 volt. Distortion of the electric field by this voltage is negligible.

Figure 2. Plan view of rotor and stator which are in the middle of the ground plane

Clearance between stator and ground plane is 3/8 inch

The presence of the 4.7-megohm resistor does not in any way affect the theory of the operation of the instrument, except insofar as the voltage of the stator does not remain at zero.

The distributed capacity of the stator and the leads to the resistor and the amplifier have been kept at a minimum, and is less than 100 micromicrofarads. However, as the stator is covered by the rotor the capacity of the stator circuit increases 300 micromicrofarads. This variation in capacity gives the stator circuit a time constant which varies from less than 0.0005 to less than 0.002 second. These times are very small in comparison with the repetition rate of 30 cycles per second, so the charge on the stator is essentially a function of the position of the rotor.

The voltage on the stator (input to the amplifier) is shown in Figures 3(A) and 3(B) for fields set up by positively and negatively charged clouds respectively. Referring to Figure 3(A), with the stator completely exposed a negative charge is bound on its surface in the presence of a positive cloud. As the stator is covered (shielded) this bound charge is released and flows to ground through the 4.7-megohm resistor. During this period the stator is negative by a voltage equal to the product of the current and the resistance. The opposite condition takes place as the stator is exposed to the electric field. When the stator is uncovered the bound charge must be replaced by a current flowing in the opposite direction and the plates are positive. It is important to note that the average voltage of the stator is zero.

A comparison of Figures 3(A) and 3(B) shows that regardless of the polarity of the electric field the input to the amplifier is exactly the same in magnitude, but displaced by 180 degrees (1/4 revolution) in time. Thus the only intelligence which may be used to determine polarity is time. A mechanical switch is so connected that the output of the amplifier is fed into the graphic and indicating instruments while the plates are being covered and is fed to ground through a resistance equal to that of the meters when the plates are being uncovered. The mechanical switch is a d-c commutator with the segments shorted to form two 180-degree arcs. The action of the commutator is shown in Figure 3(C) and its details in the insert of Figure 1. The brushes are silver-graphite type, Stackpole Carbon Company *WNS-140*, which have low contact drop and low friction making them ideal for this application. An indicating meter and a graphic meter are connected in series with the output of the amplifier so that either or both may be used. The graphic instrument is a standard Westinghouse *5 MA D-C* recording meter.

The gradient meter has been made insensitive to 60-cycle a-c fields by use of a synchronous rotor speed of 900 rpm. Since the rotor and stator are both 90-degree sectors, each incremental area of the stator is exposed to the 60-cycle a-c field for one full cycle and then covered for one full cycle, and the net effect is zero. This statement cannot be exactly true in a practical meter because of the fringing of the electric field around the edges of the rotor. Also, the mechanical switch cannot operate at exactly 180 degrees, because the brushes have physical width and allowance must be made for insulation. The net effect of these departures from an ideal circuit on this meter was that the meter indicated up to ±2 per cent of the crest value of the a-c field in a sinusoidal manner, depending on the phase relation between the a-c field and the rotor. This was reduced to ±1 per cent by filing about 3/32 inch off the edges of the rotor. This minimized the fringing effect. The meter was made completely insensitive to a-c fields by a final adjustment at the test site of the rotor position relative to the a-c field. There is no change in the indication of the instrument in the presence of an a-c field 100 times the magnitude of the unidirectional field.

The meter is housed in a water- and dust-tight metal cabinet. The stator plates are mounted on two large steatite lead-in bowl insulators. The insulators are shielded from rain and are readily accessible for cleaning. They are kept above ambient temperature, to prevent dewing on their surface, by the heat generated within the cabinet. Although the insulation requirement of the insulators is not high, since their resistance need only be large in comparison with 4.7 megohms, these precautions were taken to eliminate any possible error from this source.

A ground plane 4 feet by 4 feet is mounted on top of the cabinet exactly level with the stator plates. It was originally thought that this ground plane was sufficiently large so that the gradient on the surface of the stator would be the same as on the surface of the earth. A flux map of the electric field in the vicinity of the ground plane showed that this hypothesis was not true, and indicated that the ground plane should be extended several feet in all directions. At the time the illustrations shown in Figure 6 were taken this had not been done. The use of an extended ground plane is preferable to burying the instrument so that the stator is level with the surface of the ground. The cabinet itself is grounded to a driven ground rod.

Distortion of the field in the vicinity of the stator is reduced to a minimum by mounting the ground plane level with the stator, by keeping the voltage change of the stator to a minimum, and by mounting the rotor close to the stator. Strictly speaking, the distortion present is not important provided that it is exactly the same when the instrument is calibrated as it is in the presence of the earth's field.

The instrument was calibrated by placing an artificial cloud, a chicken wire screen 8 feet by 8 feet, 9 inches above the ground plane and parallel to it, and applying d-c voltages to the artificial cloud. The ratio of height to width of this set-up was such that the field at the stator was essentially uniform and the artificial cloud was sufficiently high so that any distortion of the field by the rotor would be the same as for a natural field.

The artificial cloud is relatively inconvenient to use, so a quick means of obtaining a check on the calibration of the

Figure 4. Schematic diagram of electronic portion of gradient meter

instrument was devised. This consists of a metal bushel basket, with an insulated metal plate mounted inside, which can be placed over the rotor and grounded to the ground plane. Provision is made for varying the potential of the plate and for reversing its polarity so that several points on the calibration of the instrument, both positive and negative, may be checked. The check calibrating device is shown in Figure 6(C).

The necessary mechanical components of the instrument were reduced to a minimum by selecting a ball-bearing 900-rpm synchronous motor with a 6-inch shaft at each end. The bearings are sufficiently heavy to take the additional weight of the mechanical switch and the rotor with the motor operating with the shaft vertical. The shafts were sufficiently long so that the rotor could be mounted on one end and the mechanical switch on the other. Standard brush-holders are used. These are supported by a rocker ring mounted directly on the motor frame. Thus all gears, extra shafts, and bearings are eliminated. It was only necessary to mount the motor so that its shaft was in the correct position relative to the stator. A brush is used to ground the shaft.

The instrument is reasonably portable. The ground plane and its supporting brackets can be removed quickly. Loops are provided through which carrying bars are placed and the instrument can be moved like a Chinese carrying chair. All parts except the ground plane remain in place.

Figure 5. Sample records obtained from gradient meter. Records not retouched

Amplifier

The electronic portion of the instrument consists of two parts, an impedance transforming pick-up unit, located close to the stator detector plates, and a 3-stage resistance-coupled amplifier unit located at the bottom of the instrument cabinet. These are shown schematically in Figure 4.

The pick-up unit is a cathode-follower stage, which serves to convert the stator voltage, which is at a high-impedance level with respect to ground, to a low-impedance level for connection to the main amplifier input. The necessity for running several feet of high-impedance lead from the detector plates to the first-stage grid is thus avoided.

The input circuit of the amplifier proper contains a resistance-capacitance filter which provides an attenuation that increases rapidly with frequencies above 30 cycles, giving the amplifier added immunity to strong 60-cycle fundamental and harmonic fields. A decade attenuator is used at the input to the first amplifier stage to provide full-scale meter deflection at gradients of 40,000, 4,000, 400, and 40 volts per meter.

The measured overall voltage gain of the amplifier proper, including the input filter, is approximately 20,000 or 85 decibels with minimum inverse feedback adjustment.

An automatic gain control circuit is provided to give an approximately logarithmic compression of the upper two-thirds of the instrument scale. This compression is accomplished by feeding the output of the second amplifier stage to a gain control amplifier whose output is rectified to provide a gain-control bias. This bias is applied to the grid of the first amplifier stage. A delay voltage is applied to the gain-control rectifier such that the lower third of the instrument scale is approximately linear. Gradients resulting in higher scale readings cause increasing reduction of amplifier gain and increased compression of the scale, with the result that full scale gradient is ten times the gradient that causes 30 per cent deflection of the instrument. This permits accurate reading of gradients varying over a wide range without a change in scale setting, an important feature in applications where the instrument is left unattended for continuous recording over long periods.

Stability of calibration and independ-

ence of tube changes is obtained by the use of inverse feedback from the output circuit to the cathode of the second amplifier stage. The amount of feedback is made adjustable to provide a small range of over-all gain control for initial calibration.

To insure freedom from motorboating and to reduce the sensitivity of the instrument to supply voltage changes, the plate voltage for the pick-up unit and the first two amplifier stages is regulated. Heavy decoupling is used in the plate circuits of all stages.

Results and Conclusions

At the time this paper was written, the instrument had been in successful operation for three months. Figure 5 shows some sample records which have been obtained, together with the weather conditions at the time of these records. The instrument is shown in Figure 6.

The authors believe that in this instrument they have combined the desirable features of a number of instruments as well as having added a few new ones. The authors do not know of any other instrument which meets all of the specified requirements, and many of these requirements have been more highly refined than on previous instruments. The operation of this instrument has been completely satisfactory and it appears to be ideally suited for its application.

Discussion

O. Naef (American Gas and Electric Service Corporation, New York, N. Y.): The authors of this paper are to be highly commended for the creation of this excellent instrument. It is one of the few graphic gradient meters which are suitable for outdoor use. Its special features make it particularly suitable for continuous operation in all kinds of weather. Its graphic records, taken at the 500-kv test project over a period of several months, have proved to be very accurate and consistent.

The construction of this gradient meter was inspired by a desire to know all the factors which may possibly explain the observed variations in measured corona losses. Such known factors are the atmospheric pressure, temperature and humidity, rain, sleet, snow and fog, and the condition of the surface of the conductor as influenced thereby.

But even under conditions which are seemingly identical the loss caused by corona is found to vary considerably from test to test.

The atmospheric gradient is one such factor which has been known to vary, but because no measuring instrument was available its effect on corona and radio interference could not be studied. It is hoped that the tests now in progress will in time show whether it has any marked influence, or whether we must be on the lookout for another, hitherto unknown variable.

Meanwhile we welcome the new gradient meter as the latest addition to our large family of recording instruments, which consists of wattmeters, voltmeters, indicators of temperature, atmospheric pressure and humidity, a rain gauge, radio influence meters, and an automatic camera, which takes pictures of moisture collecting on a sample conductor.

R. L. Tremaine and **R. C. Cheek:** The authors are pleased with Mr. Naef's discussion of the gradient meter which we designed and installed at the Tidd 500-kv corona test site. We sincerely hope that it will continue to function as successfully in the future as it has thus far, and that it may provide an answer to the question of whether corona on a practical transmission line is affected by atmospheric voltage gradient.

Solderless Commutator Joints for High-Temperature Operation of Railway Traction Armatures

J. R. REED
MEMBER AIEE

THE advent of the diesel-electric locomotive and its rapid large-scale acceptance by the railroads of the United States have brought to the fore many problems for which solutions must be found. Among the problems related to this tremendous increase in heavy d-c electric traction equipment is that of adequate joints between coil leads and commutator bars in motors subjected to severe operating conditions. This is a problem of long standing in motors operated at high temperatures, but it has become much more acute with the development and use of insulating materials that will withstand more and more heat. The first substantial increase in permissible operating temperatures of such equipment was brought about a number of years ago by the introduction of full class *B* insulation to replace the then standard class *A* or composite insulation. This permissible temperature now has been further increased by the acceptance of class *H* (Silicone)[1] insulation as standard in certain types of traction motors.

For traction motors operated at normal temperatures, the conventional solder joints between coil leads and commutator bar made with lead-tin alloys have proved satisfactory when an area large enough to provide a satisfactory conductivity of the joint is available. However, as operating temperatures have increased in value and design restrictions have decreased the available space for the commutator joint, the factor of safety thus afforded has been reduced to the danger point. This paper describes a method of eliminating entirely easily-fusible material from joints of this type.

As noted, the chief source of difficulty in commutator joints is high temperature of operation. All lead-tin solders between $2^1/_2$ and 85 per cent lead with the single exception of the eutectic alloy (37 per cent lead) have what is known as a plastic range. This is a range of temperature over which the alloy is in the form of a mush or suspension of unmelted crystals in molten metal. This is shown graphically in the lead-tin constitution diagram,[2] Figure 1. At temperatures above this range the alloy is completely liquid, and at temperatures below it, the alloy is completely solid. The eutectic alloy melts abruptly at the lower limit of this range which is constant for all alloys of these two metals within the limits mentioned. This temperature is 361 degrees Fahrenheit. It is at this temperature that these lead-tin alloys soften and begin to flow; and thus, it is at this temperature that the mechanical protection of any lead-tin solder is lost or greatly impaired regardless of the "hardness" of the solder.

Figure 1. Lead-tin constitution diagram

In armature work where full class *BBB* windings are used with a permissible operating temperature up to, or even in excess of, 300 degrees Fahrenheit, it is obvious that a solder which gives little or no protection above 361 degrees Fahrenheit leaves a negligible factor of safety for overload or other unusual conditions. This situation is further aggravated by the possibility of a high-resistance electrical joint which will cause still additional heat to be generated in the contact area of the solder.

For this reason, it has been customary to use solders with higher melting points for this class of work. Unfortunately, however, such solders are very limited in both availability and desirable properties. The most satisfactory of these has been a solder consisting of pure tin or 95 per cent tin and 5 per cent antimony. Both of these solders give protection to approximately 450 degrees Fahrenheit and are quite satisfactory for use where temperatures never exceed this limit. With the pure tin the plastic range is eliminated entirely, and in the case of the tin-antimony alloy it is reduced to a range of about 5 degrees Fahrenheit. Because of the desirability of some plastic range for ease of working, the tin-antimony alloy is most popular where hand soldering is employed. In addition, the antimony is thought to give a solder which will alloy to a greater extent with the copper being soldered, thus giving a better joint. Pure tin is used prin-

Paper 50-100, recommended by the AIEE Land Transportation Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted October 27, 1949; made available for printing December 8, 1949.

J. R. REED is a resident engineer with the National Electric Coil Company of Columbus, Ohio, at Pasadena, Calif.

The investigation of solderless commutator connections was made by the author at the San Bernardino, Calif., shops of the Atchison, Topeka and Santa Fe Railway. The author expresses his indebtedness to the Atchison, Topeka and Santa Fe Railway for their valued assistance, general supervision, and making possible the investigation and road testing; and for permission to submit this paper

cipally in solder-pot applications. These are the two solders used most widely in present practice on heavy high-speed diesel-electric traction armatures.

Even though pure tin or tin-antimony solders used with care in either hand-soldering or pot-soldering give a joint which is reasonably satisfactory for armatures insulated with standard class *B* components and operated at normal temperatures, they are not adequate for armatures insulated with class *H* (Silicone) components and operated at the still higher temperatures consistent with this type of insulation.

At present, temperatures are often attained in the operation of these armatures which exceed the melting point of this type of solder. In fact, well over 50 per cent of all armatures returned to the shops of at least one large railway have high-resistance commutator solder joint readings, and over 20 per cent require resoldering. Because of this, much work has been done to develop a solder with a still higher melting point. A number of these solders have been produced and used, particularly during the recent war when the use of tin was restricted; but, for a number of reasons, they have not been satisfactory.

Most of the high-temperature solders are primarily high-lead solders. Analysis of one solder in this class shows lead, 87.50 per cent; tin, 10 per cent; silver, 1.50 per cent; bismuth, 0.50 per cent; antimony, 0.50 per cent. Another solder has: lead, 97.25 per cent; silver, 2.50 per cent, copper, 0.25 per cent.[8] The first of these has a plastic range of 540 to 548 degrees Fahrenheit and the other has a plastic range of 550 to 580 degrees Fahrenheit. Although the melting points of these solders indicate that, from the standpoint of temperature, they are satisfactory for most applications, they still do not leave much factor of safety under present operating conditions even if they are applied with perfect results.

In practice, however, this type of solder is extremely difficult to use with consistently satisfactory results. This is primarily because of the poor spread factor, characteristic of high-lead solders. The spread factor is defined as the area in square centimeters that will be covered on clean copper when one gram of the solder is melted completely. This factor for the high-lead solders averages only about one-fifth that of the high-tin solders. For this reason, these solders are extremely difficult to flow into contacts where there is even a reasonably tight fit, such as is the case with high-speed traction armatures. However, they can be and, in fact, are being used with good results in certain types of d-c armatures where space requirements and general design are more liberal. They also are used with good results in soldering steel-wire coil retaining bands.

In the case of a particular high-speed diesel-electric armature, the electrical conductivity of the commutator joint is only about 1.5 times that of the armature bar, even when a perfect solder job has been accomplished with this type of solder. In practice, however, it has not been possible to obtain consistent soldering results which will give assurance of more than half of this amount, and even this requires careful attention to all details of cleaning, fluxing, and soldering operations with high-lead solders. For this reason, it is not possible with these high-temperature solders to obtain connections in the high-speed traction armatures under discussion, which will be consistently low in electrical resistance. As a consequence of this, heat in excess of the operating heat of the armature is liberated in the very joint which is particularly vulnerable to the effects of the high temperature; and a considerable part, if not all, of the advantage of the higher melting points of the solders is thus nullified. Furthermore, these solders are subject to oxidation as the temperature is increased, and the tendency is to produce joints eventually to high-electrical resistance. In severe operation, this brings on a vicious circle of events.

Although the use of other solders in the high-temperature range has been attempted, this has been without much success up to the present time. This is primarily because of the difficulty of getting an alloy which will flow readily into the small spaces involved and adhere properly to the copper bars with fluxes that are available for soldering operations on electric apparatus at these relatively elevated temperatures.

Figure 2. Sketch showing the use of the silver shim to tighten the coil leads in the commutator risers

The silver-cadmium solder is used to bond the top filler to the commutator risers

Tests were made with low-temperature brazing to determine if this might not possibly be a satisfactory solution to the problem. This was ruled out, however, by a number of factors. Chief among these is that the temperatures involved are destructive to the commutator insulation where such a sizable joint must be made so deep in the commutator bar as is the case with short riser bars characteristic of high-speed traction armatures where equalizer coils must often be connected actually below the level of the commutator surface. In addition to this, the work involved in milling out these connections, even if they were feasible, would so increase the cost of a subsequent rewind that this alone would make the method prohibitive.

With brazing thus ruled out, and since no suitable solder in the temperature range above 600 degrees Fahrenheit and below 700, or possibly 750 degrees Fahrenheit was available, tests were undertaken to determine if a suitable soft joint could be obtained by the use of silver plating and the complete elimination of a fused connection. With this in mind, two sets of special armature coils were manufactured incorporating a heavy silver-plated lead section in place of the then standard tinned leads. Two armatures were prepared for these coils and the commutator risers were thoroughly cleaned of all residual solder and tinning by means of a pneumatic disk sander with fine grit. Care was taken to preserve as nearly as possible the original surface of the copper bar and to avoid an irregular surface which might interfere later with the plane surface contact which it was hoped would be obtained.

After the risers were thoroughly cleaned in this manner, the inside surfaces of the riser slot were silver-plated by means of a portable silver-plating apparatus using controlled direct current and a silver-cyanide electrolyte. The current was controlled by means of surface pressure and voltage so that as nearly as possible, a bright plate was obtained. The silver was built up to a thickness of approximately 0.0005 inch and the commutator thoroughly cleaned with pure water and then baked and tested for bar-to-bar resistance. Satisfactory cleaning was achieved with the first attempt.

Following this preliminary preparation,

Figure 3. Bearing failure which allowed armature to rub on the pole pieces and practically wreck itself

the armature was wound in conventional manner with the special coils, with the exception that the commutator risers were blocked ahead of the leads being laid, and the connections were shimmed to produce a very tight circle of the risers. The material used for this shimming was fine silver shim stock rolled to a thickness of 0.003 inch and inserted in approximately every fourth or fifth riser as was needed to maintain the tight fit. The silver was used in the annealed form and was inserted as a U-shaped piece placed around the coil lead as it was driven into place in the commutator riser, as shown in Figure 2. The leads were driven into place as tightly as possible without causing appreciable upsetting of the copper. No shims were used with the equalizer winding, and these leads were actually upset into the bottom of the riser slots so as to produce a tight fit without shims. This was possible because of the relative difference in the dimensions of the equalizer leads as compared to the main coil leads and their location at the bottom of the slots.

As the winding progressed, first the equalizers and then the bottom main coil leads were "mudded in" with inorganic filled Silicone compound. This material was used to fill completely the space back of the risers to eliminate the possibility of varnish getting into the joint in subsequent impregnation. Finally as the top coils were laid as described, the remaining space behind the risers and the spaces at the ends of the cores were filled with inorganic filled Silicone compound and the armatures hot banded and wedged.

After checking the armatures for resistance in the standard manner, the remaining space in the riser slots above the top coil leads was filled in for mechanical reasons and to present a smooth contour. In the first armature this was done by brazing a copper filler into the opening with a phosphorus silver alloy material. However, as pointed out previously, this introduced the rather serious problem of stripping the armature for subsequent rewinding, and although this has not yet been done, it is evident that a softer filler would be of considerable advantage from this standpoint. For this reason, the second armature was finished by soldering the top filler into the risers with a special alloy consisting of 95 per cent cadmium and 5 per cent silver, and having a melting point between 640 and 740 degrees Fahrenheit. This solder was heated by incandescent carbon applied from the top under pressure and was fluxed with an acid-type flux used very sparingly. Actually, a small piece of the soldering alloy was placed in the slot under the filler which was deep enough to extend above the top of the risers. The carbon was applied to this filler and held until the solder melted and the filler settled into its place, see Figure 2. The results obtained in this way were very satisfactory and produced a mechanically strong bond at the top of the risers to prevent radial movement of the coil leads. The fillers could still be driven out much as the standard soldered fillers, and did not require milling or sawing as did the brazed fillers. A simple jig and carbon holder was arranged so that very little time was required for this operation.

Both armatures were vacuum pressure impregnated in the usual manner with the exception that special precaution was taken to prevent the varnish level in the tanks from coming up over the risers during the process. Final tests were completed and the resistance readings, indicating the relative conductivities of the commutator connections, showed them to be completely uniform and fully as low as the best of the solder jobs which were being tested with the same equipment.

The two armatures were placed in different high-speed passenger locomotives—the most severe application available. Both armatures were returned to the shop after approximately 60,000 miles, at which time they were put through the regular shop tests. Both armatures were checked especially to determine if there had been any changes in the commutator joints. Resistances were checked and found to be the same as when first applied and completely uniform with no high readings. After routine cleaning and checking, the armatures were again put out into the same service as before. The first armature to be rewound has not been in the shop since this first time and now has a mileage of more than 300,000 miles.

The second armature, however, was returned again after an additional 50,000 miles when the second locomotive to

Figure 4. Close-up of commutator risers of the armature shown in Figure 3

Even though commutator temperature was raised to approximately 700 degrees Fahrenheit or more, as was evidenced by the melting of the cadmium-silver solder in the top fillers, no damage was done to the riser connections

which it had been applied was in the shop for an annual overhaul. The armature was again checked carefully, and all resistance readings were found to be excellent and uniform, indicating that there had been no deterioration in the conductivity of the riser connections. There was no evidence of any excessive or localized heating as is evident in a majority of soldered armatures operated under the same conditions, even though they may not have failed. After routine cleaning and checking and reimpregnation, the armature again was placed in service on a similar locomotive where it remained in service for an additional 95,000 miles. After this additional mileage, it was returned to the shop following a complete bearing failure which allowed the armature to drag on the pole pieces and wreck itself, as is shown in Figures 3 and 4. This failure, after 206,000 miles of severe service, was not in any way the result of a winding failure, but rather was caused by a mechanical failure.

Fortunately, the commutator risers were not destroyed by the failure and were left in excellent condition for detailed inspection and study. At the time of the failure, the temperature of the commutator was in excess of 700 degrees Fahrenheit as was evidenced by the fact that the cadmium-silver solder in the top fillers had melted and run. All of the external varnish had been charred or entirely burned out. The glass-base bakelite wedges had been charred or burned out entirely. In spite of this, as was to be expected, the riser connections showed no signs of damage from the heat. There had not been any movement of the bars in the risers even at the time of failure, though the coils had been thrown from the slots in about one-fourth of the armature and had dragged on the pole pieces.

After external inspection, the coils were

cut off behind the risers and the risers themselves carefully stripped to study the nature and condition of the contact. It was found that there had been some cold welding of the silver surfaces in all of the slots while some, especially on the equalizer coils,[4] had considerable cold welding. This latter was probably due to the tighter fit of the equalizers caused by the upsetting of the copper during winding. This caused a much higher contact pressure in the constricted bottom portion of the riser slot than was obtained in the less restricted upper portions of the slots where the coils were merely wedged tightly. Some of the equalizer leads were welded so tightly that they required sawing to remove them from the slots.

There was only slight evidence of oxidation of the contact surfaces, and in no case was there any evidence of contact burning as so frequently takes place in soldered connections. There was considerable varnish in many of the contacts. This was probably due to capillary action during impregnation, by which the varnish filled the open spaces in many slots leaving free only those surfaces that were actually in solid contact. This condition should be prevented or at least minimized by more care in sealing behind the commutator before impregnation. It may possibly have been caused by improper care in one of the impregnations to which the armature was subjected during its life, and greater care in this respect also might be indicated. Actually, the presence of a varnish film in a portion of the contact area is of little consequence, because conductivity equivalent to that of the armature bar can be maintained in the commutator contact, if over 90 per cent of the available area is unused. In other words, with silver-to-silver contact, the designed factor of safety of the connection with respect to electrical conductivity is about 15 as compared to approximately 1.5 for a perfect solder contact.

In addition to this much greater factor of safety, is the fact that silver oxide between silver surfaces breaks down to pure silver at temperatures above 356 degrees Fahrenheit.[5] For this reason, it seems that electrical conductivity of the silver joint would be improved materially following subjection to temperatures which would destroy a soldered contact. These higher temperatures, if they were attained, also would tend to destroy any varnish film that might be in the contact. It also seems that repeated oxidation and reduction of even a portion of the silver surfaces accelerates to a large degree the welding of the silver to a more solid contact. This, of course, would complement the natural cold-welding characteristics of the silver which also are accelerated as the temperature is increased.

As a further practical test of this type of commutator connection, it is proposed that another ten armatures be wound in this manner and put into service under severe operating conditions as were these two.

Certainly there will be refinements in technique to improve the contacts as well as to reduce the labor involved in making them. The use of new or rebuilt commutators manufactured with silver-plated riser slots in place of tinned slots would be a big step in this direction. However, even with the present methods described in this paper, it is expected that a definite saving can be shown in labor as compared with standard soldered joints.

On the basis of the preliminary tests which have been conducted, and on the basis of the performance of the two test armatures in actual road service, it seems safe to conclude that this method of making commutator connections, although a radical departure from accepted practice, offers a practical step toward the much-needed solution to the problem of furnishing a satisfactory connection between commutator and coils for operation at temperatures above the limits of soldered joints in equipment which does not lend itself to the application of brazing. The problem, as stated previously in this paper, is becoming increasingly acute as insulations are being adopted which will materially increase the temperature limits for traction armatures. Even with the present standard insulations, a high percentage of electrical failures are caused by weaknesses of soldered connections. The high percentage of failures will certainly increase rapidly with each small increase in loading made possible by improved insulation if steps are not taken to correct the condition.

Synthetic Load for Testing Rectifiers

C. L. TETHEROW
MEMBER AIEE

WHEN metallic rectifiers are designed specifically for providing charging currents for electric storage batteries the selection of satisfactory test loads presents somewhat different problems from those normally encountered. The conventional type of ordinary variable resistance load proved unsatisfactory for this application and the need for some type of standard test load for this class of rectifier was indicated with the development of the so-called "fast-rate" battery chargers.

When speaking of "fast-rate" battery chargers, reference is made to the popular portable rectifiers which have been designated to charge the ordinary type of 6-volt automobile storage batteries at rates of from 70 to 100 amperes. Colloquially speaking, these chargers are claimed to "charge your battery while you wait". Actually they are designed to charge the average automobile battery in 40 to 60 minutes. For convenience they are provided with a pair of battery clips attached to suitable lengths of heavy-duty flexible leads so that the battery may be charged without removing it from the automobile and the connection to the source of energy is usually obtained from a generous length of power supply cord with attachment plug cap for connection to ordinary 15-ampere 125-volt outlet receptacles.

Because of the inherent low efficiency (over-all efficiency usually less than 50 per cent) of these devices, their input requirements generally border on the 15-ampere maximum allowed for portable equipment which is intended to receive its energy from ordinary 15-ampere 125-volt outlet receptacles. If input currents in excess of 15 amperes are indicated, the equipment must be provided with supply cords and attachment plug caps of suitable rating (usually 20 amperes or more) which will not fit 15-ampere outlet receptacles. Since the input requirements of this type of rectifier are dependent upon the output load, careful consideration of the proper output load is necessary in order to ascertain the input current rating.

Prior to the introduction of this particular type of rectifier, ordinary variable resistance loads had been utilized for testing rectifiers. Apparently this type of load had proved satisfactory previously and output name-plate ratings were taken at their face value when determining the output load to be used for testing purposes. The justification of the use of an ordinary variable resistance test load for "fast-rate" battery chargers was questioned and consequent investigations indicated that test procedures established previously were inadequate for this type of rectifier.

In conducting investigations, attempts have always been made to utilize test procedures which simulate as nearly as practical the actual operating conditions of the device in the field. A sincere effort also is made to maintain a minimum of discrimination between various manufacturers of similar classifications of equipment by establishing standard test procedures which are applied to all devices of a particular classification. Therefore, the problem at hand was to establish a standard test procedure for this type of rectifier which would satisfactorily maintain the foregoing policies.

Since applications were being received for investigations of "fast-rate" battery chargers with rated outputs of six volts at 100-ampere direct current, the question arose as to what minimum output voltage was actually required to charge a 6-volt battery at a 100-ampere rate. An investigation of considerable length was conducted using various sizes and ages of batteries in various conditions from completely-charged to completely-discharged status. No definite conclusions could be established from these results so as to specify any minimum charging voltage.

However, it was determined that most batteries in healthy condition (no excessive sulphation of plates or not worn out to the point where they would no longer maintain a useful charge) could be charged at a 100-ampere rate by the application of a potential from 7.2 to 8.5 volts. One exception was noted under special conditions when an output potential of approximately 6.9 volts was sufficient to charge a particular battery at a 100-ampere rate. It also was noted that under various conditions of sulphated plates, rectifier output potentials considerably in excess of 8.5 volts were required. However, when the plates of these particular batteries were sufficiently desulphated, the majority of them could be charged at a 100-ampere rate with rectifier output potentials of 8.5 volts or less.

The results of these tests indicated that the standard procedure of utilizing an ordinary variable resistance load adjusted for rated name-plate output of six volts at 100-ampere direct current was unsatisfactory. Comparative tests between resistance loads and battery loads utilizing the same rectifier at the same output potentials and currents indicated entirely different operating characteristics of the rectifier. Widely different input characteristics were noted, as well as variations in operating temperatures and efficiency. The use of an ordinary variable resistance load was thus proved to be unsatisfactory for the testing of "fast-rate" battery chargers since field operating conditions could not be satisfactorily approximated.

The only obvious alternative apparent

Paper 50-102, recommended by the AIEE Domestic and Commercial Applications Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. The author wishes to express his gratitude to H. Worthman of Hammet Electric Manufacturing Company for his assistance in this work.

Figure 1. Resistance load

at this time was the use of some type of standard batteries as a test load. In order to assure minimum satisfactory margins of safety, it appeared from previous test results that a set of standard batteries was needed which would require rectifier output potentials of approximately 8.5 volts in order to charge them at a rate of 100 amperes. Obtaining such a set of batteries was impractical for several quite obvious reasons.

Experience gained from attempting to determine what potential was required to charge a battery at a 100-ampere rate indicated that it was extremely difficult and certainly impractical to obtain two batteries with similar charging characteristics. It was further noted that any specific battery exhibited different charging characteristics each time it was charged. An investigation indicated that the following variable conditions have a distinct bearing on the charging characteristics for any given battery, namely: age of the battery; number of times cycled; rate of discharge; amount of discharge; length of time allowed to stand between charges; and condition of the battery solution.

Since so many variables of battery conditions affect their charging characteristics, the idea of attempting to use batteries for a test load was questionable. The battery load was abandoned at this time as it was apparent that there was no assurance that similar loads and test procedures would be applied to devices received from different manufacturers, or, for that matter, to different models received from the same manufacturer. It was apparent at this point that some type of test load was required which would simulate the characteristics of a battery and still maintain stable control features.

It was suggested that a high capacitance in parallel with a variable resistance could be made to approach the characteristics of a battery load. This seemed possible as it was pointed out that the capacitors would tend to retain a potential across the load at all times, thus simulating to some extent the potential maintained across the output terminals by the battery. Because of the extremely low resistance characteristics of the load, a considerable amount of capacitance is required to maintain an appreciable amount of potential across the output terminals of the rectifier. The problem of obtaining the necessary amount of capacity was not too difficult since low-voltage capacitors could be used.

Electrolytic capacitors rated at 25 volts in 10,000 microfarad capacity units were obtained. These units are contained in metal cans approximately 3 inches in diameter by $4^1/_2$ inches high. A unit containing ten of these capacitors can be housed in an enclosure having approximate over-all dimensions of 6 by 7 by 17 inches. With such a unit it was possible to experiment with capacitances of from 10,000 to 100,000 microfarad in 10,000-microfarad steps.

The entire 100,000-microfarad capacitance was found to give extremely satisfactory results from several standpoints. For identical output values of current and voltage, with identical input voltages, it was noted that the input current variation between the battery load and the capacitance-resistance load was less than 1 per cent in all cases. Comparative temperature tests were conducted and final constant temperature variations did not exceed 2 degrees centigrade in any instance. Three different types of metallic rectifiers were used during these tests and it was noted that the capacitance-resistance load caused no appreciable variations in any of the operating characteristics of the devices investigated. Reducing the capacitance from 100,000 microfarads to 50,000 microfarads caused very little variation in the input current requirements; however, oscilloscope pictures indicated some variation in output voltage wave characteristics.

Reference is made to Figures 1, 2, and 3 for typical output current and voltage wave characteristics for the three types of loads discussed. Figure 1 illustrates the wave shapes characteristic of a resistance load. The expected symmetry of wave shape is shown and it is noted that extremely high potential peaks are required in order to offset the momentary zero values and maintain an average voltage equivalent to that obtained for the other two types of test loads.

Figure 2. Capacitance-resistance load, 100,000 microfarads

Figure 3. Storage battery load

The wave characteristics typical of a capacitance-resistance load are illustrated in Figure 2. Features of these wave characteristics noteworthy of attention are the increased peak values of the current as compared to the resistance load, the small reverse currents, the peculiar current wave shapes in the vicinity of the zero current reference line, the low-peak values of the voltage wave as compared to the resistance load, and the minimum instantaneous voltage values as compared to the zero voltage reference line. It is interesting to note that maximum instantaneous current values of the capacitance-resistance load are approximately 40 per cent greater than those of the resistance load, whereas the exact reverse is true of the maximum instantaneous voltage values.

An analysis of Figure 3, which illustrates the typical wave characteristics obtained for a storage battery load, indicates some rather interesting features. A comparison of this current wave with that obtained in Figure 2 for the capacitance-resistance load shows a rather high degree of similarity with respect to maximum instantaneous values and general wave shape.

In fact, a careful analysis of the two current waves is required in order to distinguish any variations. The most pronounced difference in these two current waves appears to be in the amount of reverse current occurring during the momentary time between charging cycles. This difference is so small and of such short duration that it is considered relatively unimportant.

Although there is considerable difference between the general wave shapes of the voltages for these two loads, it is

apparent that the two are quite similar in that no excessive maximum instantaneous values are reached as in the case of the resistance load, and the minimum instantaneous values are well above the zero reference, whereas the resistance load permits the potential to drop to zero between charging cycles. The flat portion of the voltage wave for the storage battery represents the potential provided by the battery, and it must be realized that it would be impractical to supply a sufficient amount of capacitance to approach duplication of this characteristic.

A decrease in the amount of capacitance used caused an increase in the amount of variation between the maximum and minimum instantaneous voltage values and smaller reverse currents between charging cycles. Increasing the amount of capacitance used caused a decrease in the amount of variation between the maximum and minimum instantaneous voltage values and larger reverse currents between charging cycles. Therefore, it appears that the larger the capacitance used the nearer the approach can be made to the wave characteristics of the storage battery load. However, further analysis of the wave characteristics of capacitance-resistance load shows the current leading the voltage by a small angle. In order to prevent too large a phase difference between the current and voltage the amount of capacitance used must be limited accordingly. On the assumption that the power factor of the load should be maintained within certain limits, it would be necessary to vary the capacitance used in accordance with the charging rate. This would probably be considered necessary for certain research problems. It is not the purpose of this paper to attempt to establish specified amounts of capacitance for particular test loads, since the requirements for various particular problems will undoubtedly be subject to considerable variation.

Test results have actually indicated that the amount of capacitance used is not very critical. As far as input currents and temperature characteristics are concerned for the particular problem, the practical results from a 50,000-microfarad capacitance was almost as satisfactory as those obtained from a 100,000-microfarad load. Recent results obtained from a low-rate battery charger of the metallic-rectifier type have caused considerable doubt to be cast upon the importance of maintaining a specified limit on phase relationships. The entire 100,000-microfarad capacitance was used in experimenting with a battery charger whose rated output was 5 amperes, and as far as could be determined there was no appreciable effects on the operating characteristics of the rectifier. Oscilloscopes indicated an acceptable degree of similarity in output wave characteristics, and input and temperature characteristics were not appreciably affected. The phase relationship in most cases is believed to be relatively unimportant. It appears that it is more important to ascertain that sufficient capacitance is provided to maintain a substantial value of minimum instantaneous potential across the output terminals of the rectifier between the charging cycles.

Time did not permit an extension of the investigation to the point where determination could be made of what minimum amounts of capacitance might conceivably give satisfactory results or what variations in amounts of capacitance might be indicated for various charging rates. Although this particular investigation was limited to metallic-type rectifiers with maximum output potentials of 15 volts or less, it is felt that further investigation with other types of rectifiers or at greater output potentials will be required before this type of test load can be considered suitable for application to all rectifiers intended for charging storage batteries. Realizing that more extensive investigation might prove a need for varying the amount of capacitance used, the proposed standard testing procedure has been arranged to read as follows: "A suitable resistance shall be connected in parallel with the proper capacitance in such a manner as to produce output wave characteristics similar to those obtained when charging a storage battery at the prescribed rate."

Although the use of the synthetic (capacitance-resistance) load has not been formally adopted at this time, it appears to be an effective method for establishing a uniform test procedure for metallic rectifiers intended for battery-charging purposes. It is realized that the synthetic load described does not perfectly simulate the characteristics of a storage battery load; however, it appears to be considerably superior to the resistance load method, and it provides a positive means of controlling the load which is impractical to obtain by the use of storage batteries. It also provides a standard test procedure, thus enabling application of identical testing methods and loads to all equipment of this classification. In addition to the foregoing advantages it eliminates the problem and inconvenience of storing and properly maintaining a large number of various sizes of storage batteries. It is believed that the problem of selecting a satisfactory test load for metallic rectifiers intended for charging storage batteries has been satisfactorily solved by the use of the synthetic or capacitance-resistance type load.

Static Accuracy Performance of the Selsyn Generator Control-Transformer System

G. KRONACHER
ASSOCIATE AIEE

THE selsyn-generator control-transformer system, as shown in Figure 1, electrically transmits an angular position. The function of the generator or transmitter is to transform the angular position of its rotor shaft into an electrical signal. The selsyn generator is built like a synchronous 3-phase generator with laminated rotor, having either a concentrated or distributed rotor winding. The rotor winding is connected to an a-c power supply. Thus to each rotor position corresponds a definite set of three voltages between the stator winding terminals. This set of voltages is the electrical signal transmitted by the generator.

The function of the control-transformer or receiver is to transform this electrical signal into an angular position of its shaft. The control-transformer impedances are higher than those of the generator, otherwise the control-transformer is built like a generator. The rotor winding terminals are generally connected to the input of an amplifier. The signal voltages of the generator produce three currents in the 3-phase stator winding of the control-transformer. Assuming perfect conditions, the axis of the magnetic field produced by these currents would be parallel to the generator rotor axis. Therefore, the voltage induced in the rotor-winding is a measure of the angle between the generator rotor and the control-transformer rotor. Particularly, a zero rotor-voltage indicates that the control transformer rotor is at right angles with the generator rotor. This position of the control transformer rotor is defined as its position of correspondence. To obtain only one position of correspondence, the sign of the variation of the rotor-voltage when moving the rotor from its position of correspondence also must be defined.

At standstill this system would work without error if all windings were sinusoidally distributed, if the air gap were uniform and if the 3-phase system were balanced. In reality these conditions are not fulfilled, partly because of the design limitations and partly because of inaccurate manufacturing. The errors caused by inaccurate manufacturing shall not be discussed in this paper. The purpose of this paper is to calculate the inherent errors of generator and control-transformer with respect to the design data. Both the physical reason for these inherent errors as well as formulas for their calculation will be given.

The primary cause for the inherent error is the nonsinusoidal distribution of the windings. A secondary cause for errors, only attenuating or intensifying that of the primary cause, is due to the slot openings.

The following development is based mainly on the revolving field theory. At first glance this method appears as a roundabout approach since all voltages are induced by alternating axial fields. However, the alternating field when observed in time-intervals equal to the period of the a-c input appears as a static field. The generator field, corresponding to a revolving rotor, would be a fundamental field rotating with the rotor and higher harmonic fields, some rotating together with the rotor and some rotating with different speed. For each position θ of the generator rotor, Figure 1, the fundamental field together with all higher harmonic fields may be replaced by one equivalent fundamental field, which would produce the same voltage signal. In Figure 1, the real fundamental field is represented by the vector $\boldsymbol{B}_1$ and the equivalent fundamental field is represented by $\boldsymbol{B}_e$. The angle ϵ_g between these two vectors is the error of the generator. Looking at the control transformer field, there can be seen a fundamental field $\boldsymbol{B}_1'$ revolving parallel with the equivalent generator field $\boldsymbol{B}_e$ and higher harmonic fields revolving either forwards or backwards. Due to the higher harmonic fields the voltage induced in the rotor winding is not zero for a rotor position 90 degrees ahead of the vector $\boldsymbol{B}_1'$, but at an angle 90 degrees $+\epsilon_c$ ahead of B_1'. The angle ϵ_c through which the control transformer rotor has to be turned ahead of its theoretical position of correspondence with respect to the voltage signal in order to obtain zero flux-linkage in its rotor winding is the control transformer error. The sum of the generator error ϵ_g and the control-transformer error ϵ_c is the total error. It is evident that the generator error also depends on the generator load, since the voltage drop in its stator winding may influence the voltage signal.

As outlined before, the revolving field theory is the basis for the further considerations. This theory represents the total air gap field of a machine, generally a nonsinusoidal field which, while revolving, changes periodically its size and shape, in terms of a series of harmonic sinusoidal fields, each field being constant in time, but rotating in space with its proper speed. The first step in order to obtain this kind of representation is to

Nomenclature

A_ν = νth harmonic space vector of the stator point
B = air gap flux density
$\mathbf{B}_\nu$, B_ν = vector and amplitude of νth harmonic flux density distribution
$\mathbf{B}_e$, B_e, $(B_\nu)_1$ = vector and amplitude of equivalent fundamental field
C_0, C_{1s}, C_2 = Fourier coefficients of air gap permeance
$\mathfrak{F}$ = magnetomotive force
$\mathfrak{F}_c$ = magnetomotive force of one coil
$\mathbf{\mathfrak{F}}_\nu$, $\mathfrak{F}_\nu$ = vector and amplitude of νth harmonic magnetomotive force
k_ν = νth harmonic reduction factor
i_a, i_b, i_c = phase currents
n = any positive integer number
p = air gap permeance per unit area
p_0 = air gap permeance of a machine without slots
s_ν = skew factor
t = number of turns per phase of a winding
w_c = number of turns of a coil
w_s = number of series conductors of a coil side
$\mathbf{W}_\nu$ = νth harmonic winding vector
z_r, z_s = number of rotor or stator teeth
Z_l, Z_d, Z_q = load impedance, direct axis impedance, quadrature axis impedance
α = stator co-ordinate
α_n = co-ordinate of coil side "n"
β = rotor co-ordinate
γ = rotor pole arc
γ_i = ideal rotor pole arc
ϵ_g, ϵ_c = generator error, control transformer error
θ = position angle of axis of rotor coil in generator
θ' = position angle of axis of rotor coil in control transformer
$\theta_0 = \theta + \epsilon_g$
λ = mutual skew angle between rotor and stator slots
Δ = position angle of fundamental magnetomotive force field produced by a 3-phase winding
ν = order of a harmonic component of a periodic curve
$\psi_{\nu\alpha}$ = flux linkage between a νth harmonic field and a winding if both axes form an angle α

establish the flux-density distribution produced by each coil of one phase. Next the curves representing the flux densities are resolved into its Fourier components. Then all Fourier components of equal period are added together. Thus one Fourier series representing the total air gap flux of one phase is obtained. The total air gap field, created by all the phases of the winding, is obtained by superimposing the various phasefields, considering at the same time that one standing oscillating magnetic field may be represented by two equal fields constant in time and rotating in space in opposite directions. In order to consider the effect of the permeance-variations caused by the slot openings, the corresponding distortion is considered separately for each component of the resultant Fourier series. In the following development it was not necessary to consider time harmonics in the induced voltage, caused by the magnetic nonlinearity of the iron, since the position of correspondence of the control-transformer is determined by the fundamental rotor voltage only.

The Air-Gap Field

The magnetic field of a salient-pole, open-circuited generator is first analyzed under the assumption of a smooth stator surface. Later on care is taken of the distortion of the field caused by the stator slot openings. Figure 2 represents the flux-density distribution B along the rotor. In order to obtain quickly an approximate expression for the flux density, a rectangular flux-density distribution, as shown in Figure 2, is assumed. The width γ_i of this rectangle, the ideal pole-length, is determined by the condition that the total flux represented by the rectangle is equal to the real flux. For reasons of symmetry the magnetic potential drop is $+\mathfrak{F}$ for one air gap and $-\mathfrak{F}$ for the other if the total magnetomotive force for both air gaps is $2\,\mathfrak{F}$. If p_0 represents the air gap permeance per unit area the air gap flux density may be written as a Fourier-series as follows

$$B_\mathfrak{F} = \frac{4\mathfrak{F}p_0}{\pi}\left[\sin\frac{\gamma_i}{2}\cos\beta + \frac{1}{3}\sin\frac{3\gamma_i}{2}\cos 3\beta + \frac{1}{5}\sin\frac{5\gamma_i}{2}\cos 5\beta + \dots\right] \quad (1)$$

Often it is advantageous to eliminate completely a certain harmonic field. Equation 1 shows that the harmonic field of order ν disappears, if $\gamma_i\nu$ is an integer multiple of 2π. Considering that $(2\pi)/\nu$ represents the wave-length of the field of order ν, it can be stated that the harmonic field of order ν is zero, if the ideal pole-length γ_i is an integer multiple of its wave-length. Changing from rotor co-ordinates β to stator co-ordinates α according to the relation

$$\beta = \alpha - \theta \quad (2)$$

and making use of the following abbreviation

$$B_\nu = \frac{4\mathfrak{F}p_0}{\pi\nu}\sin\left(\frac{\nu\gamma_i}{2}\right) \quad (3)$$

equation 1 reads as follows

$$B_\mathfrak{F} = B_1\cos(\alpha-\theta) + B_3\cos 3(\alpha-\theta) + B_5\cos 5(\alpha-\theta) + \dots \quad (4)$$

Distortion of Magnetic Field by Stator Slot Openings

The effect of the slot-openings on a magnetic field as represented by equation 4 is two-fold. First, the permeance-variation, periodically repeating along the stator, produces ripples in the various harmonic field curves; and, second, an uneven number of stator slots destroys the original symmetry of both poles, so that the magnetic potential is no longer the same for both poles. The magnetomotive force of one air gap may be written as $+\mathfrak{F}+f$ and that of the other as $-\mathfrak{F}+f$. The value of f is determined by the condition that the total flux leaving the rotor is zero. The additional flux-density B_f corresponding to the addi-

Figure 1. Generator control-transformer system

tional magnetomotive force f, still neglecting the ripples is

$$B_f = \frac{f p_0}{\pi}\left[\gamma_i + 2 \sin \gamma_i \cos 2(\alpha-\theta) + \ldots\right] \quad (5)$$

Since f is small compared with $\mathfrak{F}$, only the first and second terms of the corresponding Fourier-series, shown in equation 5, is taken into account. Introducing the abbreviation

$$B_0 = \frac{f p_0 \gamma_i}{\pi} \quad (6)$$

equation 5 can be written

$$B_f = B_0 + B_0 \frac{2 \sin \gamma_i}{\gamma_i} \cos 2(\alpha-\theta) \quad (7)$$

The mathematical expression for the flux density curve containing the ripples caused by the slot openings is obtained by first adding equations 4, and 7 and then multiplying this expression by p/p_0. p is a periodic function of α representing the permeance between a smooth round rotor and a slotted stator. The following development is carried along for the specific case of a 15-slot stator. For that special case p/p_0 can be written as

$$\frac{p}{p_0} = C_0 + C_{15} \cos 15\alpha + C_{30} \cos 30\alpha + \ldots \quad (8)$$

Only the three terms given in equation 8 are considered in the following development. The actual value of the factors C_0, C_{15}, C_{30} may best be found from a flux plot. With equations 4, 7, and 8, the flux density can be written

$$B = \left[\left\{B_0 + B_0 \frac{2 \sin \gamma_i}{\gamma_i} \cos 2(\alpha-\theta)\right\} + \{B_1 \cos(\alpha-\theta) + B_3 \cos 3(\alpha-\theta) + \ldots\}\right] \times [C_0 + C_{15} \cos 15\alpha + C_{30} \cos 30\alpha] \quad (9)$$

The total flux per unit rotor length and radius leaving the rotor is given by the integral

$$\int_0^{2\pi} B d\alpha$$

Equaling this integral to zero, the following equation for B_0 is obtained

Figure 2. Flux density distribution in salient-pole machine

Figure 3. Magnetomotive force per unit current produced by a coil of w_c turns

$$0 = B_0 C_0 2\pi + \frac{B_{15} C_{15}}{2} 2\pi \cos 15\theta \quad (10)$$

$$B_0 = -\frac{B_{15} C_{15}}{2C_0} \cos 15\theta \quad (11)$$

First the distortion of the fields of the second parenthesis of equation 9 is to be discussed. The original νth harmonic field is transformed into the following expression

$$B_\nu \cos \nu(\alpha-\theta)\frac{p}{p_0} = C_0 B_\nu \cos \nu(\alpha-\theta) + \frac{B_\nu C_{15}}{2}\left[\cos\left\{(15+\nu)\left(\alpha - \frac{\nu\theta}{15+\nu}\right)\right\} + \cos\left\{(15-\nu)\left(\alpha + \frac{\nu\theta}{15-\nu}\right)\right\}\right] + \frac{B_\nu C_{30}}{2}\left[\cos\left\{(30+\nu)\left(\alpha - \frac{\nu\theta}{30+\nu}\right)\right\} + \cos\left\{(30-\nu)\left(+\frac{\nu\theta}{30-\nu}\right)\right\}\right] \quad (12)$$

From equation 12 it can be seen that the effect of the slot openings on the νth harmonic field is: first; to reduce slightly the original field rotating together with the rotor—C_0 is slightly smaller than 1; second, to create a field of order $(15+\nu)$ rotating in the same direction as the rotor with $\nu/(15+\nu)$ times its speed and a field of order $(15-\nu)$ rotating opposite to the rotor with $\nu/(15-\nu)$ times its speed; and third, two fields of order $(30+\nu)$ and $(30-\nu)$ respectively, one rotating forward and the other backward.

The product of the first parenthesis of equation 9 by p/p_0 can be written, considering at the same time equation 11, and neglecting the product $C_{30}B_0$ since B_0 is already a small value

$$B_0\left(1 + \frac{2 \sin \gamma_i}{\gamma_i} \cos 2(\alpha-\theta)\right)\frac{p}{p_0} = -\frac{B_{15} C_{15}}{2C_0}\left[\cos(15\theta)(C_0 + C_{15} \cos 15\alpha) + \frac{2 \sin \gamma_i}{\gamma_i} \cos 2(\alpha-\theta) \times \cos 15\theta(C_0 + C_{15} \cos 15\alpha)\right] \quad (13)$$

After some trigonometric transformations, equation 13 reads as follows

$$B_0\left(1 + \frac{2 \sin \gamma_i}{\gamma_i} \cos 2(\alpha-\theta)\right)\frac{p}{p_0} = -\frac{B_{15} C_{15}}{2C_0}\left\{C_0 \cos 15\theta + \frac{C_{15}}{2} \times [\cos 15(\theta+\alpha) + \cos 15(\theta-\alpha)] + \frac{\sin \gamma_i}{\gamma_i}\left[C_0\left(\cos 2(\alpha+13\theta/2) + \cos 2(\alpha-17\theta/2)\right) + \frac{C_{15}}{2}\left(\cos 17(\alpha+13\theta/17) + \cos 17(\alpha-\theta) + \cos 13(\alpha-\theta) + \cos 13(\alpha+17\theta/13)\right)\right]\right\} \quad (14)$$

Equation 14 shows revolving 2nd, 13th, 15th, and 17th harmonic fields. The intensity of these fields is proportional to the original 15th harmonic field. Summing up, the following expression for the total flux density is obtained

$$B = \sum_{\nu=2k+1} C_0 B_\nu \cos \nu(\alpha-\theta) + \frac{C_{15}}{2}\sum_{\theta=2k+1} B_\nu \times \left[\cos\left\{(15+\nu)\left(\alpha - \frac{\nu\theta}{15+\nu}\right)\right\} + \cos\left\{(15-\nu)\left(\alpha - \frac{\nu\theta}{15-\nu}\right)\right\}\right] + \frac{C_{30}}{2}\sum_{\nu=2k+1} B_\nu\left[\cos\left\{(30+\nu) \times \left(\alpha - \frac{\nu\theta}{30+\nu}\right)\right\} + \cos\left\{(30-\nu)\left(\alpha + \frac{\nu\theta}{30-\nu}\right)\right\}\right] - \frac{B_{15} C_{15}}{2}\left[\cos 15\theta + \frac{\sin \gamma_i}{\gamma_i} \times \left(\cos 2(\alpha+13\theta/2) + \cos 2(\alpha-17\theta/2)\right)\right] - \frac{B_{15} C_{15}}{4C_0}\left[\cos 15(\theta+\alpha) + \cos 15(\theta-\alpha) + \frac{\sin \gamma_i}{\gamma_i}\left(\cos 17(\alpha+13\theta/17) + \cos 17(\alpha-\theta) + \cos 13(\alpha-\theta) + \cos 13(\alpha+17\theta/13)\right)\right] \quad (15)$$

Figure 6 (right). 7th harmonic vector polygon for winding of Figure 4

Magnetic Field Produced by a Distributed Winding

In the theory of rotating machinery it is usual practice to calculate the magnetic field of a distributed winding by using harmonic reduction factors. The field of a distributed winding is compared to that of a concentrated winding and the ratio between the νth harmonic fieldintensity of the distributed winding and that of a concentrated winding is called differential factor. The differential factor is calculated as the product of pitch factor and distribution factor. This method is very convenient when dealing with the ordinary type of windings. The design of selsyns, however, also requires the study of irregular windings with coils of different number of turns or different coil pitches. To determine the harmonic reduction factors for odd and even harmonics of these windings a more general method is needed. It was found most convenient to study these special windings with a graphical method. The only restriction made with respect to the distribution of the coil sides is that the winding is symmetric to its axes.

Figure 3 illustrates the magnetomotive force per unit current produced by a coil of w_c turns in a round rotor machine. α_{s1} and α_{s2} are the angular distances of the coil sides from the symmetry point "O" of winding. The magnetomotive force $\mathfrak{F}_c$ per unit current of this coil can be written as

$$\mathfrak{F}_c = \frac{w_c}{\pi}\sum_{\nu} + \frac{\sin \nu(\alpha-\alpha_{s1})}{\nu} + \frac{(-w_c)}{\pi}\sum_{\nu}\frac{\sin \nu(\alpha-\alpha_{s2})}{\nu} \qquad (16)$$

Each of the two terms of equation 16 may be considered as the field of one coil side, the graphical representation of which is a straight inclined line that jumps at the center of the coil side from $w_c/2$ to $(-w_c/2)$ or vice versa, according to the direction of the current. The magnetomotive force $\mathfrak{F}$ produced by a winding is obtained by adding all partial magnetomotive forces of its coil sides. If the number of turns and position angle of any coil side are w_n and α_n the magnetomotive force per unit current can be written

$$\mathfrak{F} = \frac{1}{\pi}\left\{\sum_{n}\frac{(\pm w_n)\sin(\alpha_n-\alpha)}{1} + \frac{1}{2}\sum_{n}(\pm w_n)\sin 2(\alpha_n-\alpha) + \frac{1}{3}\sum_{n}(\pm w_n)\sin 3(\alpha_n-\alpha) + \ldots\right\} \qquad (17)$$

The positive sign in front of w_n applies to a coil side current directed away from the observer and the negative sign to a current directed towards the observer. Since the magnetomotive force is symmetric to the axes of the winding, or respectively to the origin "O" of the coordinates, $\mathfrak{F}$ also may be written in the form

$$\mathfrak{F} = \mathfrak{F}_1 \cos\alpha + \mathfrak{F}_2 \cos 2\alpha + \mathfrak{F}_3 \cos 3\alpha + \ldots \qquad (18)$$

Equalling α to zero in equations 18 and 17 and comparing the correspondent terms, the following expression results for $\mathfrak{F}$

$$\mathfrak{F}_\nu = \frac{1}{\pi\nu}\sum_{n}(\pm w_n)\sin(\nu\alpha_n) \qquad (19)$$

The total number of turns t of the winding equals one half the number of the sum of conductors per coil side.

$$t = \frac{1}{2}\sum_{n} w_n \qquad (20)$$

Introducing the harmonic reduction factor or, simply, reduction factor of order ν according to the following definition

$$k_\nu = \frac{\sum_{n}(\pm w_n)\sin \nu\alpha_n}{2t} \qquad (21)$$

equation 18 can be written in the form

$$\mathfrak{F} = \frac{2t}{\pi}\left\{\frac{k_1}{1}\cos\alpha + \frac{k_3}{2}\cos 2\alpha + \frac{k_3}{3}\cos 3\alpha + \ldots\right\} \qquad (22)$$

The νth harmonic reduction factor k_ν can be calculated from equation 21 or found by a graphical method. This method shall be explained by the example of a 15-slot winding as illustrated in Figure 4. The first step is to plot the "vector-star" of order ν. In this vector star the electrical angle, which is ν times the geometrical angle, of each slot is represented by a unit vector. The angle of the axis of the winding is assumed as zero. Figure 5 represents the vector star of order 7 for the 15-slot winding of Figure 4. Next a vector polygon is plotted as shown in Figure 6. Each side of this vector polygon corresponds to a coil side of the winding. The length of each polygon side is proportional to the number of conductors of the corresponding coil side and the direction is given by the corresponding unit vector of the vector star. The sense of the polygon side is the same as that of the unit vector if the current flows away from the observer and is reversed when the current flows towards the observer. For reasons of symmetry, the resultant of the vector polygon is prependicular to the unit vector representing the axis of the winding. The length of the resultant is proportional to the expression

$$\sum_{n} \pm w_n \sin \nu\alpha_n$$

The length of the vector polygon is proportional to twice the total number of turns, or $2t$. The length of the resultant of the vector polygon divided by the length of the vector polygon is therefore equal to the reduction factor k_ν as defined by equation 21. k_ν is positive if the resultant is turned through 90 degrees clockwise with respect to the winding axis and is negative if the resultant is turned counterclockwise. According to Figure 6, k_7 is equal to (-0.087). It can be seen from Figure 6 that k_7 becomes zero if the number of turns of the coils 3 to 12 and 5 to 14 are reduced to 63 per cent of their original value. Thus the vector polygon in general indicates how a certain reduction factor may be made zero by using coils of different number of turns. When reducing the number of turns of several coils in order to eliminate higher harmonic fields, special care must be taken in order to maintain the symmetry of the winding. It also can easily be seen that the reduction factors repeat periodically. If the center point of the winding $(\alpha = 0)$ falls into the center of a slot then the following relation exists between the reduction factors

$$k_\nu = -k_{(nz-\nu)} = k_{(nz+\nu)} \qquad (23)$$

n is any integer positive number and z is

the number of teeth of the punching, assuming equally spaced teeth. According to equation 23 the reduction factor of order 8, k_8, of the winding of the foregoing example is $+0.087$.

A similar relation exists if the center point of the winding falls into the center of a tooth. The relation is as follows

$$k_\nu = -(-1)^n k_{(nz-\nu)} = (-1)^n k_{(nz+\nu)} \qquad (24)$$

It can be seen from equation 23 and 24 that the absolute value of the reduction factors of order $(nz \pm 1)$ is equal to that of the first harmonic. All other reduction factors can be kept small or made zero by distributing the coils properly, eventually, by using coils of different number of turns. The physical reason why the reduction factors of order $(nz \pm 1)$ cannot be reduced, is that the harmonic fields of these orders are caused by the discrete distribution of the winding. These harmonics, which shall be called step-harmonics, and the steps in the graphical representation of the magnetomotive force are correlative. The reduction factors of order (nz) are all equal to zero.

$$k_{(nz)} = 0 \qquad (25)$$

Vector Representation of a Sinusoidal Field

Equation 22 represents the magnetomotive force per unit current produced by a winding symmetric to the point $(\alpha = 0)$; for instance winding "a" in Figure 1. If the axis of a winding passes through the point α_0 the expression of its magnetomotive force per unit current is as follows

$$\mathfrak{F} = \frac{2t}{\pi}\left\{\frac{k_1}{1}\cos(\alpha-\alpha_0) + \frac{k_3}{2}\cos 2(\alpha-\alpha_0) + \frac{k_3}{3}\cos 3(\alpha-\alpha_0) + \ldots\right\} \qquad (26)$$

Each of the harmonic fields of equation 26 can be represented by a vector diagram. In this diagram the magnetomotive force of the νth harmonic field at any point α is represented by the projection of a νth harmonic field vector $\mathfrak{F}_\nu$ on a νth harmonic unit space vector A_ν (Figure 7). The length of vector $\mathfrak{F}_\nu$ is proportional to the amplitude $\mathfrak{F}_\nu$ of the νth harmonic field and is rotated through ν-times the angle (electrical angle) through which the field is rotated. The νth harmonic unit space vector A_ν represents the electrical angle $\nu\alpha$ of the stator point α.

Figure 7 illustrates this vector diagram representing the second harmonic field of phase b of Figure 1.

Magnetomotive Force of a Symmetric 3-Phase Winding

The field of a symmetric 3-phase winding is obtained by superimposing the three single-phase fields, considering at the same time that the axes of two consecutive phases form an angle of 120 degrees. $\mathfrak{F}_a$, $\mathfrak{F}_b$, $\mathfrak{F}_c$ are the magnetomotive forces of the windings a, b, c and $\mathfrak{F}_{a1}$, $\mathfrak{F}_{b1}$, $\mathfrak{F}_{c1}$, are the amplitude of the fundamentals of the fields. Then the expression for the νth harmonic resultant field $\mathfrak{F}_{\nu_a}$ is, considering, equation 22

$$\mathfrak{F}_{\nu_a} = \mathfrak{F}_{a_1}\frac{k_\nu}{\nu k_1}\cos\nu\alpha + \mathfrak{F}_{b_1}\frac{k_\nu}{\nu k_1}\times\cos\nu(\alpha-120°) + \mathfrak{F}_{c_1}\frac{k_\nu}{\nu k_1}\times\cos\nu(\alpha-240°) \qquad (27)$$

The three single-phase magnetomotive forces can be written in the following form

$$\mathfrak{F}_{a_1} = \mathfrak{F}_0 + \mathfrak{F}_A\cos_A \qquad (28A)$$

$$\mathfrak{F}_{b_1} = \mathfrak{F}_0 + \mathfrak{F}_A\cos(A+240°) \qquad (28B)$$

$$\mathfrak{F}_{c_1} = \mathfrak{F}_0 + \mathfrak{F}_A\cos(A+120°) \qquad (28C)$$

Representing the three fields of equation 27 in a vector diagram, and considering equation 28, one finds the following results for the 3-phase field. The amplitude of the fields the order of which is an integer multiple of three is equal to 3 $F_0\, k_{3n}/3_n k_1$ and they are symmetric to the three phases

$$\mathfrak{F}_{3n_a} = 3\mathfrak{F}_0\frac{k_{3n}}{3nk_1}\cos(3n\alpha) \qquad (29)$$

According to equation 28, if the 3-phase currents i_a, i_b, i_c add up to zero with a star-connection $\mathfrak{F}_0$ is equal to zero. The amplitude of any other field $\mathfrak{F}_\nu$ is equal to $3/2\ \mathfrak{F}_A\ (k_\nu/\nu k_1)$. The fundamental field is rotated through the angle A with respect to phase a, while the fields of order $(3n-2)$ are rotated through the angle $+A/(3n-2)$ and the fields of order $(3n-1)$ are rotated through the angle $(-A)/(3n-1)$. In other words, the higher harmonic fields rotate slower than the fundamental field in proportion to their order and rotate alternately in the same and opposite direction as the fundamental field.

Figure 7. 2nd harmonic magnetomotive force vector $\mathfrak{F}_2$ corresponding to field produced by phase "b" and 2nd harmonic space vector A_2 corresponding to the stator point $\alpha = 45$ degrees

$$\mathfrak{F}_{(3n-1)\alpha} = \frac{3}{2}\mathfrak{F}_A\frac{k_{(3n-1)}}{(3n-1)k_1}\cos\left(\alpha + \frac{A}{3n-1}\right) \qquad (30)$$

$$\mathfrak{F}_{(3n-2)\alpha} = \frac{3}{2}\mathfrak{F}_A\frac{k_{(3n-2)}}{(3n-2)k_1}\cos\left(\alpha - \frac{A}{3n-2}\right) \qquad (31)$$

Magnetic Field Distortion Caused by the Slots

The magnetic flux density of a round rotor machine is obtained by multiplying the magnetomotive force by the permeance. To each harmonic magnetomotive force-field corresponds a magnetic field of the same order plus additional higher harmonic fields conditioned by the periodic permeance variations. These shall be called permeance harmonics. Assuming a 3-phase stator winding imbedded in a punching of z slots, the permeance can be written as follows

$$p = p_0[C_0 + C_z\cos z\alpha + C_{2z}\cos 2_z\alpha + \ldots] \qquad (32)$$

In the following development, the permeance distortion of the fundamental wave only shall be considered. The magnetic field corresponding to the fundamental magnetomotive force is according to equations 31 and 32

$$\mathfrak{F}_{1\alpha}p = \frac{3}{2}p_0\mathfrak{F}_A\{C_0\cos(\alpha-A) + C_z\cos(\alpha-A)\cos(z\alpha) + C_{2z}\cos((\alpha-A\cos(2z\alpha) + \ldots\} \qquad (33)$$

Transforming trigonometrically this equation

$$\mathfrak{F}_{1\alpha}p = \frac{3}{2}p_0\mathfrak{F}_A\{C_0\cos(\alpha-A)\} + \frac{C_z}{2}\left[\cos\left\{(z+1)\left(\alpha-\frac{A}{z+1}\right)\right\} + \cos\left\{(z-1)\left(\alpha+\frac{A}{z-1}\right)\right\}\right] + \frac{C_{2z}}{2}\left[\cos\left\{(2z+1)\left(\alpha-\frac{A}{2z+1}\right)\right\} + \cos\left\{(2z-1)\left(\alpha+\frac{A}{2z-1}\right)\right\}\right] \qquad (34)$$

Comparing equations 34, 30, and 32, it is seen that the permeance harmonics are of the same order and angular orientation as the step harmonics. The sum of both shall be considered as slot harmonics. Assuming that the phase axes pass through the center of slots, and consider-

ing equation 23, the following expression results for the slot harmonics flux density B_s

$$B_s = \frac{3}{2}\rho_0 \mathfrak{F}_A \left\{ \begin{array}{l} \left[\frac{C_z}{2} - \frac{1}{(z-1)}\right] \times \\ \cos\left[(z-1)\left(\alpha + \frac{\Lambda}{z-1}\right)\right] + \\ \left[\frac{C_z}{2} + \frac{1}{(z+1)}\right] \times \\ \cos\left[(z+1)\left(\alpha - \frac{\Lambda}{z+1}\right)\right] + \\ \left[\frac{C_{2z}}{2} - \frac{1}{(2z-1)}\right] \times \\ \cos\left[(2z-1)\left(\alpha + \frac{\Lambda}{2z-1}\right)\right] + \\ \left[\frac{C_{2z}}{2} + \frac{1}{2z+1}\right] \times \\ \cos\left[(2z+1)\left(\alpha - \frac{\Lambda}{2z+1}\right)\right] + \\ \cdots\cdots\cdots\cdots \end{array} \right\}$$

Equation 35 shows that the permeance harmonics partly intensify and partly attenuate the step harmonics. This effect may be so strong that some of the step-harmonics are completely compensated while others are doubled.

Flux Linkages of the Air Gap Field

The flux linkage of the air gap field with a coil is the air gap flux through the part of the air gap area enclosed by the coil multiplied with the number of turns, w_c, of the coil. The flux linkage is positive if the air gap flux is of the same sense as a flux produced by a positive current in the coil. The flux linkage per unit rotor radius and width with a coil, $\psi_{\nu w}$, of a νth harmonic field symmetric to the winding axis and of amplitude B_ν is: (see Figure 3)

$$\psi_{\nu w} = w_c \int_{\alpha_{n1}}^{\alpha_{n2}} B_\nu \cos(\nu\alpha) d\alpha \tag{36}$$

and evaluating this integral

$$\psi_{\nu w} = \frac{B_\nu}{\nu}[w_c \sin \nu\alpha_{n2} - w_c \sin \nu\alpha_{n1}] \tag{37}$$

The expression of the flux linkage ψ_ν of the total winding per unit rotor radius and width with the νth harmonic air gap flux is consequently

$$\psi_\nu = \frac{B_\nu}{\nu} \sum \pm w_n \sin \nu\alpha_n \tag{38}$$

w_n is the number of conductors of the nth coil side and the positive sign applies to a positive coil side current flowing away from the observer, while the negative sign applies to a current directed towards the observer.

Introducing the harmonic reduction factor k_ν as defined by equation 21, the

Figure 8. Vector representation of the equivalent generator air gap field

flux linkage can be written as follows

$$\psi_\nu = \frac{B_\nu 2t}{\nu} k_\nu \tag{39}$$

If the magnetic field axis is turned through an angle α with respect to the winding axis, the flux linkage $\psi_{\nu\alpha}$ is as follows

$$\psi_{\nu\alpha} = (B_\nu)\left(2t\frac{k_\nu}{\nu}\right) \cos \nu\alpha \tag{40}$$

It can be seen from equation 40 that the flux-linkage of a νth harmonic flux with a symmetric winding may be represented as the scalar product of two vectors. One vector, $\boldsymbol{B}_\nu$, represents the νth harmonic field as explained previously and the other vector represents the winding. This vector shall be called the νth harmonic winding vector, $\boldsymbol{W}_\nu$. The length of this vector is equal to $2tk_\nu/\nu$ and its sense and direction is that of the νth harmonic unit space vector corresponding to the axis of the winding. The angle between $\boldsymbol{B}_\nu$ and $\boldsymbol{W}_\nu$ is ν-times the geometrical, or electrical angle, between the winding axis and the flux axis. Equation 40 written with vectors is as follows

$$\psi_{\nu\alpha} = \boldsymbol{B}_\nu \boldsymbol{W}_\nu \tag{41}$$

If the slots are skewed, the flux set up by the rotor and linked with stator winding or vice versa is obtained by multiplying the expression of equation 42 with a νth harmonic skew factor s_ν. If λ is the skew angle, the centric angle between two corresponding slot points at both rotor or stator faces, the skew factor is given as

$$s_\nu = \frac{\sin(\nu\lambda/2)}{\nu\lambda/2} \tag{42}$$

If both rotor and stator slots are skewed, the mutual skew angle has to be substituted in equation 42. The general expression for the flux linkage of a skewed winding is consequently

$$\psi_{\nu\alpha} = s_\nu(\boldsymbol{B}_\nu \boldsymbol{W}_\nu) \tag{43}$$

The Equivalent Flux

Comparing, on base of a vector diagram, the three flux linkages of a 3-phase winding produced by a revolving fundamental flux with the flux linkages produced by a revolving higher harmonic field, the following relation can be established: considering the flux linkages of a symmetric 3-phase winding, a νth harmonic field of amplitude B_ν and rotated through the angle α_ν is equivalent to a first harmonic field $(\boldsymbol{B}_\nu)_1$, of amplitude $(B_\nu\ s_\nu k_\nu)/(\nu s_1 k_1)$ rotated through an angle $(\nu\alpha_\nu)$ in the same direction if ν is equal to $(3n\text{-}2)$ and in the opposite direction if ν is equal to $(3n\text{-}1)$. A revolving field of order $\nu = 3n$ produces equal flux linkages in all three phases.

$$(B_\nu)_1 = \frac{B_\nu s_\nu k_\nu}{\nu s_1 k_1} \tag{44}$$

Thus replacing all higher harmonic fields by their respective equivalent fields, the whole nonsinusoidal field may be replaced by one fictitious equivalent fundamental field. Generally the vector representing this equivalent field is not in line with the axis (if there is any) of the nonsinusoidal field. Only if the axis of the nonsinusoidal field lines up with one of the phase axes the equivalent field is in line with the nonsinusoidal field.

Errors Caused by the Generator

First it shall be assumed that the generator is connected to a balanced load, the impedance of which is high compared with that of the generator. In that case the stator armature reaction may be neglected. Then the error caused by the generator simply is the angle between the rotor axis and the axis of the equivalent rotor field. The calculation of this error shall be shown on an example, considering only the 1st, 5th, and 7th harmonic of the rotor field. Figure 8 shows the vector diagram of the 1st harmonic field B_1 and the equivalent fields of the 5th and 7th harmonics $(B_5)_1$, and $(B_7)_1$. According to the vector diagram, the error is a function of 6θ. The analytic expression for this error angle $(\epsilon_\theta)_6$ is

$$\tan\ (\epsilon_\theta)_6 = -\frac{(B_5)_1 \sin 6\theta + (B_7)_1 \sin 6\theta}{B_1 + (B_5)_1 \cos 6\theta + (B_7)_1 \cos 6\theta} \tag{45}$$

With equation 44 and considering that $(\epsilon_\theta)_6$ is a small angle and that $(B_5)_1$ and

$(B_7)_1$ are small compared to B_1, equation 45 may be written as follows

$$(\epsilon_g)_4 \approx \left\{ -\frac{B_5 k_5 s_5}{5B_1 k_1 s_1} + \frac{B_7 k_7 s_7}{7k_1 s_1 B_1} \right\} \sin 6\theta \qquad (46)$$

Assuming a generator winding as shown in Figure 4, a skew angle of 24 degrees, and a salient pole rotor of 90-degree pole arc, the parameters of equation 46 are as follows

$$B_7/B_1 = -1/7; \quad k_1 = 0.916; \quad k_5 = 0; \quad k_7 = -0.087; \quad s_1 = 1.0; \quad s_7 = 0.68$$

Substituting these values into equation 47, the maximum 6th harmonic generator error results in 0.0013 radian.

All errors caused that way are of the order $3n$. This is a consequence of the symmetries of a 3-phase winding. The general expression for the error of order $3n$ is

$$(\epsilon_g)_{3n} = \left\{ -\frac{B_{(3n-1)} k_{(3n-1)} s_{(3n-1)}}{B_1 (3n-1) k_1 s_1} + \frac{B_{(3n1+)} k_{(3n+1)} s_{(3n-1)}}{B_1 (3n+1) k_1 s_1} \right\} \sin (3n\theta) \qquad (47)$$

If there is a distributed winding on the rotor, the ratios $B_{(3n-1)}/B_1$ and $B_{(3n+1)}/B_1$ may be expressed by harmonic reduction factors according to equation 22. If the index r refers to the rotor and s to the stator, equation 47 transforms into

$$(\epsilon_g)_{3n} = \left\{ -\frac{k_{(3n-1)r} k_{(3n-1)s} s_{(3n-1)}}{(3n-1)^2 \; k_{1r} k_{1s} s_1} + \frac{k_{(3n+1)r} k_{(3n+1)s} s_{(3n+1)}}{(3n+1)^2 k_{1r} k_{1s} s_1} \right\} \sin (3n\theta) \qquad (48)$$

Equation 48 shows that in order to obtain a good selsyn generator, the products of the harmonic reduction factors of rotor and stator should be small. In other words, the stator winding should be insensitive to all harmonics to which the rotor winding is sensitive.

Additional Generator Errors Caused by the Slot Openings of the Rotor

As can be seen from equation 34 and the subsequent discussion, the main effect of the rotor slots is to intensify one part of the step-harmonics and to attenuate the other part. Consequently, the errors caused by these step harmonics are intensified or attenuated in proportion. This effect has to be taken into account if one wants to compensate against each other the errors caused by two step harmonics. For instance, according to equation 48, both the 11th and 13th field harmonic of a 12-slot rotor cause a 12th harmonic generator error. It would be possible to choose the reduction factors of the stator-winding so that both errors cancel each other. However, the slot openings may, for instance reduce considerably the 11th harmonic field and increase the 13th harmonic field, changing thereby the picture completely. In this special case, equation 48 is unreliable. Equation 47 has to be used and the intensity of the 11th and 13th harmonic fields has to be calculated according to equation 35. If however, according to equation 48, the error caused by a certain field harmonic is zero, the slot openings do not change this. Likewise, if the error of a certain harmonic is very small, the slot openings do not cause much change and may be neglected. In order to keep the slot harmonic errors small, these harmonics must be either matched with very low stator-reduction factors or the slots must be skewed so as to obtain a small skew factor.

Additional Generator Error Caused by the Stator Slot Openings

Equation 15 shows the additional revolving harmonic fields, caused by the slot openings of a 15-slot stator. Replacing the additional fields, caused by a νth harmonic rotor field, by their equivalent fields, it can be seen that they cause an error of the same order as does the νth harmonic field. The effect of the stator slots, therefore, is merely to intensify or attenuate the errors caused by the original rotor field harmonics. Mostly this effect is weak and may be neglected. Only the error due to original harmonics, the order of which equals that of the stator slot harmonics, may be changed considerably by this effect. In that case, several of the additional fields are of the 1st order and therefore may cause a strong additional error.

The error caused by the 15th harmonic, generally by a harmonic of order equal to the number of stator teeth, needs special consideration. As can be seen from equation 15, this harmonic causes an additional 12th and 18th harmonic error. In general this additional error is very small and may be neglected.

Additional Generator Errors Due to Armature Reaction

The armature reaction in a salient pole generator, that is, the effect of the field produced by the stator currents, causes an additional error. There are two causes for such an additional error. First, a fundamental magnetomotive force in the stator produces beside a fundamental magnetic field also higher harmonic fields. These higher harmonic fields rotate together with the rotor and are practically in time phase with the rotor field because of the inductive generator load. Therefore, they simply intensify or attenuate the corresponding rotor harmonic fields as well as the errors caused by them. Obviously, this effect only becomes important if the strength of the field produced by the stator approximates that of the rotor, that is, at very low generator load-impedance.

Secondly, an additional error is caused by the assymmetry of the generator reactances. The quadrature reactance of a salient pole machine is considerably less than its direct axis reactance. The fundamental field of the rotor magnetizes in the direct axis, whereas the errors are caused by fields or field components magnetizing in the quadrature axis. The corresponding direct and quadrature currents are inversely proportional to the total direct and quadrature impedances of the system. If the load impedance is Z_l, the generator direct and quadrature impedances respectively Z_d and Z_q, the generator error under load ϵ_{gl} is, assuming all impedances as mainly inductive

$$\epsilon_{gl} \approx \epsilon_g \frac{Z_l + Z_d}{Z_l + Z_q} \qquad (49)$$

Errors Caused by the Control Transformer

The currents induced by the equivalent generator field produce a corresponding field in the control transformer. The field of an ideal control transformer would be sinusoidal and its axis would be parallel to that of the equivalent generator field. Then the position of correspondence of the control transformer rotor, position for zero rotor voltage, would be exactly $\pi/2$ ahead of the equivalent generator field. However, the control transformer stator windings also produce, beside the fundamental field, higher harmonics. The rotor position for zero flux-linkage, θ', is therefore ahead of the equivalent generator field by an angle equal to $(\pi/2+\epsilon_c)$; ϵ_c is the control transformer error. The position angle of correspondence of the control transformer is therefore

$$\theta' = (\theta + \epsilon_g) + (\pi/2 + \epsilon_c) \qquad (50)$$

The position angle of the equivalent generator field $(\theta+\epsilon_g)$ shall be written as θ_0.

$$\theta_0 = \theta + \epsilon_g \qquad (51)$$

The control transformer error can be calculated by establishing the expression of the rotor flux-linkage ψ_r' and equating

it to zero. In the following the rotor flux linkage caused by the fundamental flux $\boldsymbol{B}_1$ and the harmonics of order $(3n+1)$ $\boldsymbol{B}_{(3n+1)}$ and of order $(3n-1)$, $\boldsymbol{B}_{(3n-1)}$, shall be considered. If $\boldsymbol{W}_1$, $\boldsymbol{W}_{(3n-1)}$ and, $\boldsymbol{W}_{(3n-1)}$ are the respective winding vectors of the rotor winding, the flux linkage can be written according to equation 41 as

$$\psi_r' = s_1\boldsymbol{B}_1\boldsymbol{W}_1 + s_{(3n+1)}\boldsymbol{B}_{3n+1}\boldsymbol{W}_{3n+1} + \boldsymbol{B}_{(3n-1)}\boldsymbol{W}_{(3n-1)}s_{(3n-1)} \quad (52)$$

Figure 9 shows the vector diagrams corresponding to equation 52. According to these diagrams, the condition for zero rotor flux linkage is

$$0 = B_1k_{1r}s_1\cos(\theta'-\theta_0) + \frac{B_{(3n-1)}k_{(3n-1)r}s_{(3n-1)}}{3n-1}\times \cos(\theta_0+(3n-1)\theta') + \frac{B_{(3n+1)}k_{(3n+1)r}s_{(3n+1)}}{3n+1}\times \cos(\theta_0+(3n+1)\theta') \quad (53)$$

With equations 50 and 51 and considering that $B_{(3n+1)}$ and $B_{(3n-1)}$ is small compared with B_1 and ϵ_e is a very small angle, the control transformer error of order $3n$ results as

$$(\epsilon_e)_{3n} \approx \left\{\frac{B_{(3n-1)}k_{(3n-1)r}s_{(3n-1)}}{B_1\quad(3n-1)k_{1r}s_1} - \frac{B_{(3n+1)}k_{(3n+1)r}s_{(3n+1)}}{B_1\quad(3n+1)k_{1r}s_1}\right\}\times \sin\left(3n\theta_0+\frac{3n\pi}{2}\right) \quad (54)$$

Expressing the ratios $B_{(3n+1)}/B_1$ and $B_{(3n-1)}/B_1$ by harmonic reduction factors according to equation 22 and writing θ instead of θ_0, since ϵ_e is a very small angle, the control transformer error can be written as follows

$$(\epsilon_e)_{3n} \approx \left\{\frac{k_{(3n-1)}k_{(3n-1)r}s_{(3n-1)}}{(3n-1)^2\,k_{1r}k_{1r}s_1} - \frac{k_{(3n+1)}k_{(3n+1)r}s_{(3n+1)}}{(3n+1)^2\,k_{1r}k_{1r}s_1}\right\}\times \sin\left(3n\theta+\frac{3n\pi}{2}\right) \quad (55)$$

Equation 55 for the control transformer error is very similar to equation 47 for the generator error. If both the generator and control transformer of a selsyn system have the same windings, except of its total number of turns, then the maximum error of a given order is the same for both machines. The errors of order $(12n-6)$ add, that is the maximum system error is twice the maximum error of either machine. The errors of order $(12n)$ cancel each other. The errors of order $(6n-3)$ add in quadrature, that is the generator errors are sine functions of θ and the control transformer errors are cosine functions. The corresponding system error is $\sqrt{2}-$ times the error of either machine.

Figure 9. Representation of the magnetic field vectors B_1, $(B_{(3n-1)})_1$, and $(B_{(3n+1)})_1$, and of the winding vector W_1, $(W_{(3n+1)})$, $(W_{(3n-1)})$ for a control transformer

Additional Control Transformer Error Caused by Stator Slot Openings

According to equation 35 the effect of the stator slot openings is either to intensify or attenuate several step harmonics. This means that the errors, the order of which is an integer multiple of the number of stator slots are either intensified or attenuated. If the rotor winding is insensitive to the stator slot harmonics, then the slot openings do not cause any additional error.

Additional Control Transformer Error Caused by the Rotor Slot Openings

The main effect of the rotor slot openings is to distort the fundamental field. If the rotor has z_r teeth, then the fundamental field will be accompanied by a pair of harmonic fields of order (z_r+1) and (z_r-1) and another pair of order $(2z_r+1)$ and $(2z_r-1)$ and so forth. These additional fields rotate together with the fundamental field and induce in the stator windings an additional voltage. For instance, the 13th harmonic field caused by a 12-slot rotor acts on the stator like an equivalent fundamental field revolving forward with 13 times the rotor speed. The voltage induced by this equivalent field causes an opposite fundamental field. This field is somewhat weaker than the equivalent field because of the leakage reactance and the generator reactance. From the previous explanations, it is obvious that this field causes an additional 12th harmonic error. Generally it can be stated that the rotor slot openings either increase or decrease the errors, the order of which is an integer multiple of the number of rotor teeth. If the stator winding is insensitive to the rotor slot harmonics, then the rotor slot openings do not cause any additional error.

Summary

The design of an accurate selsyn generator or control transformer may be accomplished by considering equations 47 and 48 or 55 respectively. The slot openings only increase or decrease certain errors given by these formulas. If according to these formulas a certain harmonic error is small or zero, the slot openings also cause a small or zero additional error. Exception of this rule has to be made only in the case that the errors caused by two different harmonic fields cancel each other. All errors of order $(6n-3)$ can be avoided by making the rotor or stator winding insensitive to even harmonics. Therefore the winding also has to be symmetric to a line vertical to

Figure 10. Generator error curve b and control transformer error curve a

its axis. This is only possible if the punching contains an even number of slots.

Curve *a* in Figure 10 shows a control transformer error curve. It corresponds to a control transformer with a 2-slot round rotor and a 15-slot stator winding, as shown in Figure 4. The 6th-harmonic error is caused by a 7th-harmonic flux and should reach, according to equation 55, an approximate maximum of 0.0013 radian, or 4.5 minutes. The actual 6th-harmonic error is 3.7 minutes. Curve "*b*" shows the error curve of a generator with a 15-slot stator winding and a salient pole rotor of 90-degree pole arc. The 6th-harmonic error has been eliminated by using a stator as before but coils of different number of turns. Thus it was possible to obtain a 7th harmonic reduction factor equal to zero. The 12th-harmonic error is caused by the 11th-harmonic field. The 2nd-harmonic error is caused by manufacturing inaccuracies.

The inherent error of the differential selsyn, that is, a selsyn with 3-phase winding on stator and rotor, can be treated by the same method. Moreover, it may be mentioned that an additional accuracy error is caused by manufacturing errors. Also an inherent dynamic error is present if the selsyn generator moves with considerable speed or acceleration.

However, it was not intended to discuss these additional phenomena in this paper. References 2 and 3 discuss some of these aspects.

Discussion

A. E. Blume and R. W. Votaw (General Electric Company, Schenectady, N. Y.): Mr. Kronacher is to be commended on a very general and rigorous treatment of the inherent errors present in selsyn generators and control transformers. The use of the revolving-field theory has one outstanding feature. If we have a flux component (using Kronacher's symbols) $B_{n,m}\cos(n\alpha-m\theta)$, n determines the maximum number of flux linkages in the secondary and so determines the maximum induced voltage. m determines how this voltage varies with θ, and so determines the order of the error caused. The harmonic reduction factors for all harmonics can be determined by calculating those for the first $z/2$ harmonics (z even) or the first $(z-1)/2$ harmonics (z odd). The skew factor for any harmonic is easy to calculate. Then K_nS_n/K_1S_1 determines the flux linkages and therefore the voltage induced by $B_{n,m}\cos(n\alpha-m\theta)$ as compared to the fundamental voltage produced by $B_1\cos(\alpha-\theta)$.

There are several points that should be made about the second and third sections of the paper. In the first place the condition that

$$\int_0^{2\pi} B d\alpha = 0$$

is true but not enough. The selsyn generator, like most a-c machines, is nearly a constant flux machine. Thus, in addition to the above condition, there should be a condition that

$$\int_{-\pi/p}^{\pi/p} B d\beta = \text{constant}$$

Stated in words, the flux out of a pole at the same time every cycle on the exciting current wave is constant. What happens is that the exciting current can and will vary when the total reluctance seen by the primary changes. Thus the magnitudes of the various magnetomotive-force components can change when the rotor of a generator is revolved.

In the section on The Air-Gap Field, Mr. Kronacher discusses the variation of the ideal pole-length, γ_i. In the section on Distortion of Magnetic Field by Stator Slot Openings, Mr. Kronacher carries along γ_i, but it is no longer a variable, since the equations are for a smooth, round rotor, which means a rotor with a pole are approaching 180 degrees. For a salient-pole rotor the permeance considering both the rotor and a slotted stator would be

$$p = [p_0 + p_2\cos 2(\alpha-\theta) + p_4\cos 6(\alpha-\theta) + \ldots]$$
$$[c_0 + c_{15}\cos 15\alpha + c_{30}\cos 30\alpha + \ldots\ldots]$$

p_2 is roughly half of p_0 and p_{2n} is approximately equal to p_2/n, so that the first series does not converge very fast. These additional permeance terms would make the equations for the salient pole case much more complicated than those for the round rotor. Furthermore, there is a question as to the validity of the conditions

$$\int_{-\pi/p}^{\pi/p} B d\beta = \text{constant}, \qquad \text{and}$$

$$\int_0^{2\pi} B d\alpha = 0 \text{ in the salient pole case}$$

The flux must leave or enter the pole face at right angles, or practically so. However, if r is the radius from the center of the rotor to the pole face, there is no particular necessity for the flux to cross the circle of radius r at right angles between the poles. It would appear that there might be some modification (and probably a very complicated one) that must be made to the two conditions.

All of these points are relatively unimportant as far as the merit of the paper is concerned. Mr. Kronacher has shown how inherent error can be avoided. Practical windings have been developed by the General Electric Company following the principles developed in Mr. Kronacher's paper and machines using these windings now are in production. The 6th harmonic of error is not present in these machines; in fact, there is effectively no inherent error.

There remain, however, two problems which must be solved before the reduction in inherent or design errors so obtained can be fully exploited. In the first place, errors due to asymmetries such as mechanical eccentricities, out-of-roundness, unbalanced resistances, and so forth, which are unavoidable in the actual machine are frequently as great or greater than the design errors in even a machine using a conventional stator winding with the same pitch and number of turns for each coil. This problem can be attacked by changing mechanical design or improving production methods and control or possibly by electrical means of reducing the effect of mechanical asymmetries.

Even if this problem is solved, an additional difficulty is caused in practice by the so-called "null voltage" at correspondence. Theoretically, correspondence is the position of the control transformer rotor at which the control transformer output voltage is zero, a condition which never occurs in an actual machine. There always remains a voltage, consisting partly of higher time harmonics and partly of fundamental voltage in time quadrature with the normal rotor output voltage at a position off correspondence. In theory, servo amplifiers can be designed to reject such signal inputs from the selsyn system, but in modern practice, with the emphasis on reduction of the size and weight, nonlinearities exist in the amplifier which cause it to respond to these extraneous signals. This second selsyn problem is then the old story of "increasing the signal-to-noise ratio."

Past practice has been to reduce the transmitted error and increase the signal-to-noise ratio by using a 2-speed selsyn system where one generator-control transformer pair is operated at higher than load speed for fine control and another pair is operated at load speed to remove the possibility of the first pair being in correspondence while the director and load are not. Until practical solutions for the two additional problems discussed above are obtained, 2-speed systems will continue to be necessary for accurate work.

G. Kronacher: I studied with great interest the thorough discussion presented by A. E. Blume and R. W. Votaw.

I agree with their first statement that the flux passing through the rotor is constant. The selsyn error, however, is not dependent on the amount of flux but only on its distribution. The flux distribution may change with the magnitude of the flux because of iron saturation effects. It can, indeed, be observed that the angle of the selsyn generator signal slightly varies with the magnitude of the input voltage.

The equations of the section Distortion of the Magnetic field by Stator Slot Openings were intended to be valid both for salient-pole and round-rotor generators. As pointed out by Blume and Votaw, equation 8 is correct for points under the pole arc only and is completely wrong for points of the interpole space. However, it was stated previously that the flux of the interpole space shall be neglected. This assumption was introduced mathematically by expressing the flux density for a smooth stator in a Fourier series representing the rectangular curve shown in Figure 2. The final flux density distribution is obtained as a product of two functions, namely the rectangular flux density distribution expressed by equation 5 and the ratio between the real permeance and that for a smooth stator as expressed by equation 8. It does not matter that the second factor is wrong for all points of the interpole space because the first factor is zero for all these points of the interpolar spaces. Of course the method used in this scheme is an approximation only.

I agree with Blume and Votaw that it is of equal importance to minimize errors caused by manufacturing tolerances and to reduce the null voltage. An analysis of the causes of these errors would certainly be very interesting, but is beyond the scope of this paper.

Electrical Hazards to Farm Stock

W. B. BUCHANAN
MEMBER AIEE

THIS paper is a brief summary of various points of interest in the supply of electric power to stock farms. Cases of data given are derived from actual field experience and should be of interest to inspectors and consumer service representatives. The need for careful study is emphasized not only in the initial installations but for periodic reinspections to ensure maintenance in safe condition.

About six years ago this subject was presented to the AIEE as a problem which seemed to warrant a more critical study than had, at that time, been given to it by this Institute. The channel through which the request was made indicated that many important groups, having high responsibilities, were interested and the interest would be widespread, possibly even global.

A subcommittee was organized under the Committee of Domestic and Commercial Applications and the co-operation of a group of engineers solicited, some of whom were not members of the Institute. Named only as a fact-finding committee, it was not only advisable but necessary to be content with passing on such information to those in authoritative positions for interpretation in action at their own discretion.

Information has been obtained from many sources. The writer's most intimate knowledge of the problems arose from the fact that during the year 1943 a large number of cases occurred in the Province of Ontario, Canada, where valuable cattle were killed while standing in their stalls and investigations were made by The Hydro-Electric Power Commission of Ontario to determine the causes in each case. These cases were apparently very similar to other cases reported from areas where climatic conditions and dairying practices closely parallel those in Ontario, namely, Wisconsin and Minnesota.

A study of the various components of this problem led to a further continuous study of various features of its distribution system by The Hydro-Electric Power Commission of Ontario. This paper constitutes simply a plea for more and better engineering in the supply of electric power to farm buildings. There has been evidence of a rather widely held opinion that extension of electric service to farms has been merely an extension of the practices and standards of construction common in urban centers, regardless of local conditions, and there seems to have been some justification for such a view.

The majority of fatalities reported were derived from the modern practice in dairy stables of supplying drinking water to the stalls through iron pipe, the use of metal piping for operating milking machines and the use of steel stanchions as enclosures. Such conditions present a 24-hour-a-day hazard in case of electric potential being set up at the stanchions and an animal cannot possibly withdraw to safety. Cases have occurred with animals in other locations and human fatalities also have occurred.

While the owner is normally the principal financial loser in these cases the utility and also the general public are vitally concerned with the safety to life and property involved in the distribution of electric power. Codes for standard practice have been developed and in some cases have statutory authority for their enforcement. We know something of the efforts of Code committees to formulate standards that may prove workable and of value. Notwithstanding all effort of the part of officials to ensure installations free from hazard, it has been well-nigh impossible to eliminate risk even on new equipment. Where the various deteriorating effects due to age, and so forth, are added the need for careful inspection and possibly test by the owner or his adviser becomes apparent. An intelligent inspection requires some knowledge of basic data and ability to estimate conditions in quantitative terms. Some of these features have been studied in considerable detail.

Safe Limits of Voltage and Current

Popular opinion seems to indicate that standard distribution voltages can be handled with little care but this is unwarranted; a large number of bathroom fatalities testify to that fact.

A great deal of investigation has been conducted toward determining what might be adopted as safe currents and voltages and at what values such units might prove fatal. For obvious reasons it is not permissible to go to the limit in experiments on human beings. Valuable information on maximum let-go currents, body-resistance, and so forth, have been obtained on normal men and women and this type of test can be repeated in almost any well-conducted laboratory.

Experiments have been made on animals up to and including lethal dosages in connection with studies on resuscitation. Further studies have been made on a comparison of body-weights to anticipate what a lethal dosage for a human being might be, but such a method of substitution is too highly conjectural to be reliable.

A summary of investigations made where farm stock have been killed tends to indicate that 32 volts (less than one-third of normal service voltage) applied between the nose or shoulders of a cow and her feet may prove fatal; that 20 volts (less than one-fifth normal service voltage) between metal stanchions and the floor of the stalls has set up violent commotion among the animals in a stable

Paper 50-104, recommended by the AIEE Safety Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted February 9, 1950; made available for printing February 9, 1950.

W. B. Buchanan is Research Adviser with The Hydro-Electric Power Commission of Ontario, Toronto, Ontario, Canada.

and that about 12 volts (or less than one-tenth normal service voltage) between a drinking trough and the floor of a stall is sufficient to prevent an animal drinking and hence interfere with proper feeding and milk production.

Other records tend to indicate that for healthy adult human beings, maximum let-go currents are of the order of 12 to 15 milliamperes (less than 1/50 of the current taken by a 100-watt lamp) with lethal values anywhere above 25 milliamperes even with current interrupted at frequent intervals. Involuntary muscular response, however, occurs at as low current as $1^1/_2$ to 2 milliamperes (less than 1/500 of the current taken by a 100-watt lamp) and in hazardous locations might initiate a serious accident.

These figures are introduced to emphasize the need for absolutely preventing the straying of current by devious and unauthorized paths, hence the need for high quality of installation and maintenance, and the advisability of adhering to recognized codes insofar as these codes deal with safety in operation. A breakdown in the insulation of a conductor may enliven metallic parts with which man or beast normally comes readily in contact and such locations may be quite remote from the fault itself.

Earth Potentials and Current Paths

There are a number of features associated with electrical hazards that do not appear to be well understood, certainly not where all the various ramifications of the problems are taken into account. The most important of these probably is associated with so-called grounding of circuits and other metallic parts of electric equipment.

The conductivity of earth varies over a wide range of values and also, so far as this problem is concerned, with seasonal changes. If current is discharged to ground, it is practically impossible to prevent it taking unauthorized and frequently dangerous routes in its return circuit. These sneak currents and voltages are particularly hazardous because they are usually unsuspected and their action very prompt. The difficulties of the engineer arise from the fact that earth conductivities are usually sufficient to carry the lethal currents noted above but not high enough to cause interruption of the power supply by blowing fuses or opening circuit breakers. Fire hazards also can be created with very low values of stray current and voltage.

An assumption frequently made is that if current is led to earth by metallic rods or water pipes it would therefore be harmless. As a matter of fact the current must dissipate through fairly large areas of earth before the voltage drop around such grounding metals can be entirely neglected. For this reason a high concentration of voltage drop or voltage gradient may occur adjacent to rods or pipes of small diameter.

The practical application of this phenomena has many ramifications, for example, a lightning rod ground should be separated at least six feet from the ground rod to which any conduit or motor frame may be attached. Otherwise a lightning stroke can cause, and has resulted in a breakdown of the insulation of the wiring in such conduit.

The flexible steel-armour of a 2-wire circuit was installed under a floor in a cottage and was grounded at both ends, yet sufficient stray current passed through this steel armour to heat it and set fire to adjacent wood work on two occasions.

A cow was walking quietly through a gateway alongside a barn and dropped to the ground and expired. A piece of loose iron wire was found embedded in the surface of the earth over which she walked, and one end of the wire was attached to conduit on the wall of the barn. The insulation on a wire of the circuit in the conduit had failed and the conduit and wire were electrically alive.

A fault on a range in a residence caused potential to be applied to a waterpipe which led underground (in contact with soil) about 200 feet to the stable. Fifty volts was measured between the waterpipe, which was attached to the stanchions, and the floor of the stalls where six cattle had been killed.

Water-Piping for Grounding Purposes

The value of water-piping for grounding purposes in rural services is frequently much over-rated, if considered at all. In addition to the low conductivity to earth as indicated in the example previously noted, various objectionable conditions such as the following have been discovered.

Many such water-systems have no contact with earth whatever, some only slightly and then in fairly dry locations. It is quite common to find the water-piping carried overhead from its entrance to the stable to its termination at the stalls.

Electrical discontinuities occur in the piping due to various causes. Breaks in malleable T-couplings have been mended with tape. One hundred ohms was measured between the incoming and outgoing pipes from a float-tank from which water-bowls were supplied; unions and other couplings may have high resistances. In fact it is possible to assemble a union in a 1/2-inch pipe to introduce 100 ohms when full of water; the piping to and from either wooden or concrete tanks may not be directly connected at all; grounding clamps unless carefully cleaned and fitted may be found to result in quite high resistances to the pipe.

Other cases, associated with summer cottages perhaps to a greater extent than on farms, have indicated lethal hazards where none were suspected. A boy swimmer in a river attempted to grasp the suction pipe to an electrically-driven pump while there was a breakdown in the motor insulation and was electrocuted. Ninety volts was measured within the length of his body adjacent to the pipe.

A collie dog stepped on a water pipe which led from a cottage out along the sandy beach into the water for some distance and was killed. The motor had for some years been removed in the fall and replaced in the spring and the insulation at the terminals had become weakened and failed.

A grounding pipe installed at a boathouse was driven into the soil below about five feet of water and was in contact with water directly for that five feet as well. With 115 volts applied, however, this ground would not permit enough current to flow to blow fuse wire of 1-ampere rating.

Deterioration

There are certain features and practices which seem to be more characteristic of rural installations and though the immediate risk may be negligible, the effect of deterioration of insulation and other material should be given some thought. It would be difficult to list these in the order of their importance nor would the list be complete, but some items of more than passing interest may be mentioned.

Pump-motors have been found installed in wells, metallically connected to piping. Insulation on such motors also has failed, with temporary wiring offered as an explanation. Other installations of a safer type involve separation of the motor from the pump by wooden platform and belt-drive or by wooden operating rod on the pump jack.

The humid atmosphere occurring at times in stables has a deteriorating effect on insulation at various locations but

principally if moisture is allowed to collect in conduit leading in from colder atmosphere. The best simple remedy against collection of moisture seems to be to avoid any possible traps in the conduit, or provide automatic drainage.

The merits of nonmetallic sheathed cable versus metal conduit is a subject of controversy. As a matter of fact, it should be possible to do a good job using either system but the essential requirements cannot be ignored. Among other things, nonmetallic sheath should be fungus-resistant, have good abrasion and shock resistance and have slow flammability. The insulation over-all should be moisture-resistant, have good tensile strength and reasonable life. One case occurred recently where a 1/2-inch water pipe wore through the insulation of a nonmetallic sheath cable and 18 purebred cows were electrocuted. This wiring had been installed about six years.

More than ordinary care is necessary to ensure good current carrying capacity in conduit. Corrosion of joints between conduit and boxes may be accelerated by the application of lime or other disinfecting washes used in stables. A recent field investigation showed that 45 volts existed across a length of less than three feet where three such joints were involved. Had these joints, and the others in the conduit run, been of good conductivity, undoubtedly the animals in the stables would have been subjected to voltages of dangerous magnitude. The cause of this stray voltage was found to be a corroded connector between the high-voltage neutral conductor and the grounding lead.

Another class of trouble arises from conductors so loosely supported that they may be whipped together in the wind or otherwise make accidental contact with exposed metal parts. Loosely strung lines across the yard may develop a short circuit. Hazards are multiplied when barns or other buildings are covered with metallic siding.

One outstanding criticism may be made which would be applicable to many of the cases reported, for example, an attempt to make alterations or additions to the system without due regard to all conditions as they existed at the time, in effect, incorrect procedure due to incomplete or incorrect diagnosis. This may be observed all up the line from the amateur who installs a single-pole switch in the neutral or grounded lead of a circuit to more complex cases in which the work was carried out by experts. One such case occurred when eight cows were killed. The contractor very conscientiously provided a grounding wire (third conductor) and connected it from the frame of the milking machine back to the switch panel at the entrance to the stable. The conduit carrying the power wires was grounded but not connected to the neutral. Insulation failed in the conduit and potential was carried by way of the frame of the milking machine to the stanchions where 80 volts was set up within length of any one animal.

Another case resulted in the electrocution of two cows because the contractor made wrong assumption as to the manner in which the utility normally brought out terminals and neither party actually made check tests before enlivening the circuit.

Strange as it may appear some of the installations made over 30 years ago with the knob-and-tube-system of open wiring were in better condition than many with metalclad wiring less than ten years old.

It should be evident from this brief examination of factors involved in the problem of supplying electric power with safety that very little carelessness can easily introduce a high degree of hazard. Various proposals for protection have been made, some of which are of doubtful value. Others have controversial aspects which are desirable under some conditions and undesirable under others. A proper appraisal of the various factors becomes quite an involved problem—a job for specialists. Even when all is done that can possibly be accomplished by standardization and mandatory codes, it appears that hazards will still continue. Many of these will doubtless be repetitions of what has occurred before and new types may develop.

Whatever else may be done to improve safety, it seems clear that periodic inspection of equipment by specially-trained inspectors would be desirable. In any case alertness and continual vigilance should be exercised by those who recognize hazardous conditions to see that any such hazards be brought to the attention of the proper authority.

No Discussion

Protective Grounding of Electrical Installations on Customer's Premises

A. H. SCHIRMER
MEMBER AIEE

THE problem of electrical safety in rural areas is one of providing adequate insulation on circuits and equipment, and effective grounding and bonding. Providing adequate insulation presents no particular problems. However, there is some confusion as to what constitutes effective grounding and bonding. This paper briefly discusses the various factors which must be taken into account. The discussion is limited to a-c circuits.

Purpose of Grounding

The purpose of grounding is: to limit or reduce potentials that would otherwise exist between conductors and equipment; to limit the voltage between conductors and their metal enclosures; and to provide a path for fault currents of sufficient magnitude to cause overcurrent devices to operate and de-energize the circuit.

It is well known that limiting potentials reduces the likelihood of electrical shock to persons and animals, and much emphasis has been placed on this point. What is not so well known is that limiting or preventing potentials by grounding, reduces the possibility of insulation failure and arcing, and thus also reduces the fire hazard.

Voltages Involved

There are ordinarily three sources of voltages for which protection must be provided: (1) lightning; (2) primary distribution, 2400 volts or above; and (3) secondary distribution, that is, 120–240 volt circuits.

Relative Importance of Protection from Primary and Secondary Voltages

In the early days when electricity was used primarily for lighting and convenience outlets, and appliances were practically unknown, the main reason for grounding secondary circuits was to reduce the hazard resulting from primary voltages. Today, with better transformers and transformer protection, as well as improved pole line construction, faults involving primary circuits are relatively rare. On the other hand, more and more appliances are being used in the home and factory so that protection from low-voltage faults has become the more important consideration. It seems wise, therefore, to discuss low-voltage protection in detail, particularly since the grounding and bonding required for adequate low-voltage protection is in general adequate for primary voltage and lightning protection.

The National Electrical Code[1] requires secondary circuits to be grounded if they can be so grounded that the maximum voltage to ground does not exceed 150 volts. Except in public water pipe areas it is in general not practicable to secure a grounding electrode which has a resistance of less than 10 ohms. In view of this, satisfactory low-voltage protection cannot ordinarily be obtained where separate grounding electrodes are used for circuits and equipment. This is illustrated by the following examples. The conduit mentioned in these examples may be considered as any metallic enclosure for conductors or equipment.

EXAMPLE 1

Conditions

Neutral of 120–240 volt circuit connected to a 10-ohm grounding electrode. Conduit connected to a 20-ohm grounding electrode. Fault between live conductor and conduit.

Result

Fault current 4 amperes; 15-ampere fuse did not operate. Conduit remained energized at 80 volts.

Remarks

This method of grounding is obviously unsatisfactory for low-voltage protection. Additional secondary grounds at the transformer or elsewhere on the secondary system would not help the situation since the current would remain under 6 amperes.

EXAMPLE 2

Conditions

Neutral of 120–240 volt circuit and conduit connected to a common 25-ohm electrode. Fault between live conductor and conduit.

Result

Fault caused a short circuit; fault current large; fuse blew quickly; voltage on conduit small.

Remarks

This method provides adequate low-voltage protection.

EXAMPLE 3

Conditions

Neutral of 120–240 volt circuit and conduit connected to a common grounding electrode having a resistance R_1 ohms. In addition, a grounding electrode having a resistance of R_2 ohms is connected to the neutral at the transformer pole. Fault between live conductor and conduit.

Results

Fault caused a short circuit, fault current large; fuse blew quickly. If the resistance of the electrode at the service (R_1) is large compared to the resistance of the electrode at the transformer (R_2) the voltage of the conduit to ground may

Paper 50-105, recommended by the AIEE Safety Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted March 8, 1950; made available for printing March 15, 1950.

A. H. SCHIRMER is with the Bell Telephone Laboratories, Inc., New York, N. Y.

approach 60 volts, that is one-half of the secondary voltage until the fuse blows.

Remarks

This method also provides low-voltage protection.

Common Grounding Electrode

From the foregoing example it is evident that to have good low-voltage protection, it is necessary to have a common ground for circuits and equipment at each building served. Section 2554 of the 1947 edition of the National Electrical Code makes such common grounding mandatory.

The use of a common grounding electrode is important from the standpoint of lightning and also for faults involving primary circuits in order to prevent excessive voltage between conductors and equipment enclosures. It might be pointed out that insulation failures resulting from lightning, where separate grounding electrodes are used for circuits and equipment, are a frequent cause of conductor or equipment enclosures becoming and remaining energized from secondary voltages.

Interconnection of Grounding Electrodes

Safety may be further improved by so arranging the grounding that all metallic structures, which can be touched or to which arcing might occur, are connected to or from part of the same grounding electrode used for grounding the circuit. If all grounded-metallic structures within a building are connected to the grounding electrode used for grounding the electric circuits, no large difference in potential can develop within the building. In recognition of this fact, it has long been the practice of power companies to bond together all metallic parts within a generating or substation area. Such interconnection also is approximated where a water piping system is used as the grounding electrode, as discussed below.

Reason for Using Water Pipe Grounds

In urban areas, the use of underground metallic piping systems as a grounding electrode is well established. The reasons why such water pipes provide the best grounding electrode and why it is necessary to use them for grounding the circuit are well expressed in a paper, Electrical Grounds on Water Pipes, by H. S. Warren.[3]

He states as follows:

"The reason why a continuous metallic public supply water piping system makes the best ground is not because such pipes have water in them but is due to the fact that such a piping system has by far the largest contact surface with the conducting material of the earth. In fact, where such a piping system exists, it is the earth, electrically speaking, for all practical purposes. The hazard to be protected against arises from the fact that voltages may accidentally be set up between different metallic objects in the house and that persons may be subjected to these voltages. Water pipes appear at numerous points through the house and are interconnected or in contact with steam pipes, gas pipes, and so forth, so that they offer numerous chances for people to get in contact with them. If some other grounding electrode were employed instead of the water pipes, the voltages between electric wiring, apparatus, and so forth, and this extensive system of pipes might be much larger and, hence, the hazard much greater. The very presence of these piping systems in a house increases the importance of using them as grounding electrodes."

Where so-called private water systems, that is systems supplied from local wells, are used, the presence of the water piping system in a building presents, in varying degrees, the same situation as outlined in Mr. Warren's statement. It is recognized that, in general, the resistance to ground of such systems will be materially larger than for public systems. It is nevertheless important to use such a system as the grounding electrode or to bond it to any other electrode which may be used.

There are several reasons:

1. The use of such piping systems for grounding purposes, regardless of their resistance to ground, reduces the likelihood of difference of potential within a residence.

2. If the water system is not used as the grounding electrode, large differences of potential may occur between the electric wiring and the piping system due to lightning, particularly in rural areas. Since it is difficult to have large separations between the water pipes and electric wiring, arcing due to lightning will occur at points of small separation. Such arcing, with power arc follow-up, constitutes a greater fire hazard than lightning alone where power wires are not involved.

3. Most private water systems today have an electric pump with the motor frame in contact with the piping system. If the wiring system is not connected to the water piping systems, large potentials may develop between the winding and the frame of the motor due either to lightning or a fault involving the primary circuit. Such potentials frequently cause insulation failure and a cross between the live circuit conductor and the frame. Where the resistance of the water pipe is more than a few ohms, such a fault will not operate the branch fuses and the water pipe will remain energized at a voltage approaching 120 volts.

Interconnection of Primary and Secondary Neutral

It is evident, of course, that the grounding connection should have a resistance as low as it is practicable to obtain. Bonding the secondary neutral to a multigrounded primary neutral reduces the resistance of the secondary neutral to ground and has definite advantages both from the standpoint of lightning and faults involving a primary distribution circuit. With properly designed multigrounded primary circuit, the normal potentials due to load currents are ordinarily small. At any rate, if the potential to ground due to normal load current is larger than seems wise, the answer is to improve the grounding on the primary neutral circuit, rather than to separate secondary and primary. The National Electrical Safety Code[2] permits the interconnection of the primary and secondary neutrals. It states in Rule 285c:

"Primary and secondary circuits may utilize a single conductor as a common neutral if such a conductor has at least four ground connections in each mile of line. Ground connections at individual services are to be counted only if made to underground water piping systems."

Section 2632-a-2 of the National Electrical Code also provides for such interconnection.

Farm Barns

While the writer does not claim to have complete statistics on farm animal fatalities, such cases as have come to his attention were largely due to sustained secondary voltages on conduits or piping systems. These sustained voltages resulted from the fact that the circuit, conduit, and equipment were not grounded to a common grounding electrode at the barn. In rural areas it is important that the circuit and enclosures be grounded at each substantial building served. In many of the cases the failure of the conductors in the service conduit (at the barn) caused the sustained potential. These failures in the service conduit were probably caused by high lightning potentials between conduit and conductors resulting from the fact that the circuit either was not grounded at the barn or was not commonly grounded to the conduit grounding electrode.

Potentials which persist for only a very short time do not ordinarily constitute a substantial hazard, and there is very little evidence that such momentary potentials have been a major factor in farm animal electrocutions. It must be admitted, however, that in a dairy barn

where the stalls are provided with automatic drinking cups, the likelihood of electric shock to cattle is greater than it would be without the automatic cups. If there is concern, the way to solve the problem is to bond and ground all extensive metallic structures in a barn and place in each stall or group of stalls some metallic structure under or in the floor and bond such structure to the piping system. The metallic structure should be so located that the potential at the rear of the stall will be the same as at the front of the stall. With such an arrangement the cow may be at a substantial voltage above ground, but there would be no damaging current through the body of the cow.

No Discussion

Rural Neutral Potentials

J. H. WAGHORNE
NONMEMBER AIEE

THIS paper covers the results of an investigation of potentials occurring on the neutrals of the rural distribution lines of The Hydro-Electric Power Commission of Ontario. Having regard to the potentials under normal operation, unusual loads, primary faults, and lightning surges, the conclusion drawn is that the common multigrounded neutral is the safest and most reliable ground available in the distribution system and that normally all metallic enclosures should be connected to it.

Background of the Investigation

The Commission's Rural Systems

The Hydro-Electric Power Commission of Ontario owns and operates 32,000 miles of rural distribution lines serving 260,000 consumers. Approximately 55 per cent of this mileage carries 25 cycles-per-second power, and the balance 60 cycles per second. About 8 per cent of the total mileage has single-phase distribution transformers connected phase-to-phase on a grounded-star 3-wire system, but this is gradually being displaced by using the multigrounded neutral common to primary and secondary. This neutral is grounded at each distribution transformer, and on each consumers' premises. Although the lines have an average of more than eight consumers per mile, some sections are ungrounded for as much as two miles.

All of the 8 per cent phase-to-phase distribution is at 4,000 volts, along with 44 per cent of total mileage with multigrounded neutral. These lines serve the more densely populated areas. The 8,000-volt system (4,600 volts phase-to-neutral) covers 43 per cent of the rural mileage at present, and in time will replace more of the 4,000-volt system. For long lines in more sparsely populated areas, 12,000 volts (6,900 volts phase-to-neutral) is generally used. At present, this includes 5 per cent of the total mileage.

Grounding Regulations

Before 1931 the consumers' grounds were not connected to the neutral even on grounded neutral lines. Service boxes, conduit, and all other metallic enclosures were required to be connected to a driven ground for "safety." Service entrance boxes installed since 1931 have been connected not only to a driven ground but also to the neutral. Distribution boxes in other buildings continued to be connected to "safety" grounds but not to the neutral until 1947. This means that all metallic enclosures connected to the service entrance boxes during this period have been tied to the common neutral while those not so connected have been protected only by "safety" grounds. Since 1947 revised wiring regulations for rural areas require that all metallic enclosures be connected to both the neutral at the distribution box and a driven ground rod.

Reason for Investigation

Primarily to investigate the extent of the hazard involved in the connection of metallic enclosures to the neutral, the Electrical Research Department of the Commission has been and is investigating the primary neutral potentials which exist or can occur on its rural lines. The use of a common primary and secondary neutral obviously applies any primary neutral potential to whatever metallic enclosures are connected to it.

If metallic enclosures are not connected to the neutral but only to driven rods for "safety" the sum of the driven rod resistance to earth and the secondary neutral to earth resistance must be low enough to clear secondary fuses in case of secondary faults. This means a maximum combined resistance of less than five ohms. If this is not obtained, a fault from a 110-volt conductor to any metallic enclosure may fail to blow the fuse and the fault is sustained. Depending on the ratios of resistances involved, some fraction of the 110 volts remains on the enclosure. Where water systems and steel stanchions in stables are connected to such enclosures this voltage can prove fatal to farm stock. The Commission, as well as others, has had first-hand experiences of this nature.

The investigation of neutral potentials has included four different conditions: normal operation; unusual loads; primary faults; and lightning surges.

Normal Operation

Survey of Farm Areas

A survey in 1945 indicated that lethal voltages do not normally exist on the primary neutrals throughout farm areas. In general, where land is good for farming, creating heavy electrical loads, it is also good for grounding; conversely, where grounding is poor due to rock or light soil, farming is less productive and farm electrical loads lighter. The search for possible neutral potentials was made through a farming area about 100 by 350 miles. Two graphic voltmeters were used to obtain fortnightly charts at 20 locations where the largest neutral potentials would be expected and an indicating voltmeter was used to check an additional 56 lines.

The maximum potential recorded near the end of a line was 17 volts. This was found in dairy farming country and was the result of a combination of factors: large milking machine and grain grinding load, too small neutral conductor, and very few consumer grounds connected to the neutral, as the line was one of early

Paper 50-106, recommended by the AIEE Safety Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted March 8, 1950; made available for printing April 19, 1950.

J. H. Waghorne is with The Hydro-Electric Power Commission of Ontario, Toronto, Ontario, Canada.

Figure 1. Map of Southern Ontario showing locations of rural neutral potential measurements

construction. Regulation of the line was very unsatisfactory, hence this condition would not normally be permitted to continue. Adjacent to the distribution station, 19 volts was found at one location and 16 volts at another, which calls attention to the fact that voltage can appear at either end of a line. At the load end of the lines from these stations, no appreciable voltage was measured.

One other line was found with a maximum of seven volts but all others checked in farm areas were below five volts.

Summer Resort Areas

In 1946, the survey of neutral potentials was concentrated on lines serving summer resort areas. For this survey, 15 graphic voltmeters with ranges of 14 and 28 volts were purchased. In resort areas the possibility exists of poor grounding due to rock or sand and gravel, while the electrical loads during the summer may be heavy. Graphic voltmeter measurements were made at 31 locations where load and grounding suggested the possibility of neutral potentials, and in 1948 an additional 10 locations were checked. From this total of 41 locations, nine were found with voltages at times reaching values above 10 volts. Three of these reached above 25 volts, one of which was above 28 volts for 5 per cent of the time, see Figure 1.

Reduction of Neutral Potentials

In many areas throughout the province where grounding is poor, sand or gravel overlies clay. If ground rods are driven through the sand or gravel into the clay, good grounding is usually obtained. For this purpose extension rods are used, threaded at both ends to permit them to be fastened together with a short coupling. Driving is done with a standard gasoline-driven pavement breaker adapted to fit the threaded ground rods. The longest rod driven to date was 210 feet. Laboratory and preliminary field tests indicate that hardened steel tips and just a tapered fit for couplings instead of threads would facilitate driving considerably.

Long rods were driven on the only farm line found with appreciable voltage, one to a depth of 94 feet, and the maximum neutral potential was reduced from 17 to 11 volts. At one of the two distribution stations found with appreciable neutral voltage, four ground rods were driven to a depth of more than 50 feet. At two summer resort locations, long rods were used to bring down the neutral potentials in 1948.

In 1949 the use of long rods was extended, 4,912 feet of rod being driven at about 100 locations in the area including Deanlea, Wymbolwood, New Wasaga, Wanakawening, and Nottawa beaches. The voltage at these locations before improvement is shown in Figure 2. Checks after improvement showed none of these going above five volts.

At one summer resort location where as high as 28 volts was recorded, grounding is poor because bedrock is only a few feet below the surface. No holes or crevices in the bedrock can be readily located near enough to be effective. In this instance the single phase is to be changed to 3-phase, which will reduce the primary neutral current. However, a heavier primary neutral conductor would also have been effective in reducing the neutral voltage to a safe value.

Considerable confidence has been gained through this investigation in the possibility of maintaining all rural neutrals at safe potentials under normal load conditions. If an exception be found, isolation of the secondary neutral from the primary could be a second choice.

Unusual Loads

Open-Star-Open-Delta

At one location a 40-horsepower 3-phase load was supplied from two phase conductors and the neutral through an open-star-open-delta transformer bank. This line ran about five miles from a 3-phase supply to this load but a maximum of eight volts was measured on this neutral at the end of the line and nine volts was measured at the distribution station.

Ground-Return Circuit

In another area a few miles of single-phase circuit with transformers connected from primary to grounded neutral using underground cable is fed from a 3-wire 3-phase distribution line several miles from the distribution station. As the star point at the station was grounded all the neutral current from the single-phase grounded section was forced to return to the station via the earth. Only one volt was measured on this section of neutral.

Wide Separation of Phases

Where two different phases travelled by widely separated routes as single-phase lines from the distribution station to within one-half mile of each other no appreciable neutral potential was found on the end of either line.

Large Concentrated Single-Phase Load

The Village of Newburgh is fed single-phase power from an 8,000-volt 3-phase line by carrying the 4,600 volts phase-to-neutral about three-quarters of a mile to the village limits. At this point a 75-kva single-phase transformer reduces the line voltage to 2,300 volts and the line then continues for three-quarters of a mile to the village center where the main part of the load is located. The conductor in the 2,300-volt section is number 2 copper and when carrying the maximum load, a drop of about 30 volts is produced along this neutral. Since the neutral resistance is less than one ohm and the grounding resistance at the transformer is much greater than this, there is no appreciable current carried in the earth.

As only one point on a conductor carrying current can be at true ground potential, this neutral cannot be maintained at a low potential throughout its length. The need to change to 3-phase for a concentrated load of this magnitude is indicated.

Fault Conditions

In evaluating the possible hazards from common neutral potentials, the results of primary faults must be considered. The most serious types of fault are phase-to-neutral short circuits, breaks in the neutral, and the combination of both.

Line Used for Experiment

The line serving a farm area around Roseville, was found from the survey as having unfavorable grounding and was chosen for fault tests. This line is 3-phase for $1^1/_2$ miles and then single-phase for an additional $4^1/_2$ miles, number 6 copper phase and neutral, operating at 2,300 volts. It is an old line and consequently has few consumer grounds. In the last 1.7 miles of single-phase there are nine transformers with a ground at each having resistances ranging from 4 to 100 ohms.

Phase-to-Neutral Short

With a short circuit between phase and neutral applied through a 15-ampere fuse at the end of the line, 370 volts was measured on the neutral for 0.8-second duration. With 15 extra consumer grounds connected (as there would be under more modern construction) 204 volts was measured.

A short circuit applied 1.7 miles from the end of the line with no extra consumer grounds connected produced 220 volts at the point of application and 135 volts at the end of the line for a duration of 0.4 second.

Phase-to-Neutral Short Plus Open Neutral

With the neutral broken 1.7 miles from the end of the line short circuits were again applied at the end and 445 volts was measured on the neutral without extra consumer grounds and 225 volts with such grounds.

Primary Neutral Open

Under normal load with the neutral broken 1.7 miles from the end of the line, 19 volts would be the maximum neutral potential. At another location where the neutral was accidentally broken, leaving only three transformers on the end section feeding summer cottages, the neutral potential measured was only 2.4 volts.

Lightning Surges

Surge Voltage Recorder

The development of a simplified klydonograph-recording unit in the Commission's laboratories has greatly facilitated the collecting of field data on surges. In two rural areas a total of 400 units has been serviced for three lightning seasons.

Installations

In order to determine the frequency of surges on the rural neutrals 76 klydonograph installations were made from neutral to a separate ground connection at the distribution transformers and 70 installations between neutral and ground at consumers' equipment.

Results

These records have been plotted in two curves, as shown in Figure 3, showing the frequency of occurrence of surges larger than a given value on the primary neutral and also at the consumers' equipment. As the majority of these surges originate on the primary, attenuation is evident by the time they reach the consumers' equipment. This is particularly the case with the larger surges which would have steeper wave fronts and tails. Equipment located close to the transformers would be subjected to the surges indicated at the transformer, hence this curve should be used to determine possible frequency of surges on secondary equipment connected to the neutral.

It can be seen from the curves that 38 per cent of equipment will receive surges above 10,000 volts each year, 15 per cent above 20,000 volts, and 6 per cent above 30,000 volts.

Evaluation of Hazard from Neutral Potentials

The classification of voltages is still not very definite with respect to degree of nuisance, or probable lethal effects. The accumulation of information of this type is necessarily slow, as for obvious reasons lethal limits for human beings cannot be set by experiment and would be expensive to obtain for the larger domestic animals. A few cases have arisen where evidence of neutral potential has been given by cattle refusing to drink from water bowls that were connected through

Figure 2. Potentials measured with graphic voltmeter on rural neutrals at lettered points shown on map of Figure 1

Figure 3. Frequency of lightning surges measured with klydonographs between the rural neutral and an independent ground

the private water system to the neutral. The lowest voltage recorded to date causing this nuisance is seven volts.

For sustained power frequency voltages where the exposure may be severe as in stables or around water pumping systems, and so forth, a fair amount of evidence has accumulated in favor of a classification such as:

0–7 volts, possible nuisance
7–25 volts, probable nuisance
25–50 volts, possibly lethal
50–110 volts, probably lethal

The hazards involved in exposures of short duration are even more highly conjectural than for sustained potentials. The amount of evidence available is more scanty and is somewhat conflicting. However, very much larger voltages apparently can be safely withstood for periods of the order of a fraction of a second than for sustained periods. Against this is some evidence that the phase of the heart cycle at the instant of application of the shock is a controlling factor on the result.

The hazards may be evaluated under the four operating conditions:

Normal Operation: Under normal operation, neutral potentials can be maintained at safe values without undue expense.

Occasionally potentials will be experienced large enough to be a nuisance. In these cases if it is not practical to reduce the maximum potential to less than seven volts separation of primary and secondary neutrals can be used. If in the future the neutral potential condition is remedied reconnection can be made easily.

Unusual Load Conditions: While no unusual load conditions producing serious neutral potentials have been found on the Commission's rural systems during these tests it would not be safe to conclude that such instances will not arise. Hence all such conditions should be individually checked.

Fault Conditions: If primary phase-to-neutral faults were sustained they would no doubt lead to lethal voltages. However, when their slight probability of occurrence is multiplied by the small probability of the existence of severe exposure and by a reduction factor resulting from their short duration, the chance of the neutral potential having lethal consequences is reduced to a very small undetermined value. As the Commission has been operating with a small percentage of the consumers' metallic enclosures connected to the common neutral for 17 years with only a single fatality as yet from this cause, some confidence has been gained that the hazard involved is very slight.

Lightning: Much the same arguments apply with regard to lightning as for fault conditions. One additional factor is that the most severe lightning surges will flash over to metallic enclosures even without interconnection, and have been doing so for years without adding any fatalities to our records.

Conclusion

Nearly all fatalities of farm stock investigated by the Commission from 1943 to 1949 resulted from a sustained fault to metallic enclosures on consumers' equipment. These metallic enclosures were connected to driven rods as "safety" grounds which failed to clear the circuits. Such faults would have cleared the circuit had the enclosure also been connected to the neutral.

Investigation of neutral potentials indicates that the common primary and secondary multigrounded neutral can be safely used for grounding purposes.

Wiring regulations for rural areas in the Province of Ontario were amended in 1947 to require all metallic enclosures on future installations to be connected to the common neutral and to driven grounds.

Discussion

W. B. Buchanan (The Hydro-Electric Power Commission of Ontario, Toronto, Ontario, Canada): This paper is a contribution to the work of the fact-finding committee in which the writer has been interested during the last few years. It serves to call attention to various factors involved in the problem rather than to establish limiting conditions.

It is only fair to point out that the operators of the system on which these results were taken have been highly alert to the grounding problem in all its ramifications for at least 25 years to the writer's knowledge, and from the point of view of maintenance the system might be considered as one of the best if not the best in existence.

In the interests of safety, however, it seems prudent to call attention to some possibilities which indicate that the cases given do not warrant final conclusions as to operating practice.

The writer personally investigated a case of a break in the primary neutral, where 110 volts persisted through most of an afternoon from the primary and secondary neutrals to ground at periods of light loads. Shocks were obtained by operators at gasoline pumps and the condition existed some days before being reported. This was in a moderately well settled suburban section with grounds mainly in clay loam. Fortunately, no serious accident resulted from this case.

It would be unfortunate from the point of view of safety to disregard the possibility of lethal potentials occurring on primary neutrals. The writer has definite information of two unsuspecting linemen (other cases have been reported) being fatally shocked by coming in contact with the primary neutral and ground only. There are very definite reasons for the use of guards on ground wires and other suitable protection of man or beast in exposed locations.

One may not assume that transient overloads of the nature of short circuits will always be of negligible duration. Arcing-grounds can be rather vicious in setting up potentials in and around so-called grounded structures.

Care must be taken that bonding of all metallic objects in contact with earth does not become a fetish rather than sound engineering. There is frequently a great deal of metal equipment around farms that has nothing whatever to do with the electric service and which, if tied in therewith, could introduce serious potential hazards. Those entrusted with the formulation of mandatory codes should recognize such conditions as being possible and not put the electrical inspector in the embarrassing position of having to violate code regulations in order to make equipment safe. Waghorne mentions the fact that the primary and secondary neutrals could be separated as a second choice.

Obviously, there is need for a permissive clause on this point in regulations; also for one to provide for isolation of the iron-piping in the stables if that should prove to be the best and safest solution.

The listed values of nuisance and lethal values require some analysis. Data available indicate that seven volts is a nuisance if applied to an animal under certain conditions, also that 30 volts is a lethal value. The terms "possibly" and "probably" thus refer to the chance that an animal (or person) may make contact in such manner as to allow the voltage to become fully effective. The writer had occasion some years ago to take measurements on the equipment used for electrocuting dogs and cats. The sustained potential between a metal collar around the dog's neck and the metal floor on which it sat was only 60 volts. The hair and skin of the neck was wetted to improve contact conductivity. There was never any doubt as to whether 60 volts was lethal or not.

Gaps for Voltage Measurement, The Irradiation of Spark. Hardy, Craggs.....584–90
Gas Pressures, Loading of Hydrogen-Cooled Generators at Elevated. Snell.....186–99; disc. 199
Gas-Turbine Electric Locomotive, Control System for a 4,500-Horsepower. Warrick.....508–13
Gas-Turbine Electric Locomotive, Rotating Electric Equipment for a. Coho.....514–18
Gas-Turbine Electric Locomotive, The Alco-GE 4,500-Horsepower. Morey.....504–07
Gauge Using Beta Rays, Noncontacting Thickness. Clapp, Bernstein.....488–90
GE 4,500-Horsepower Gas-Turbine Electric Locomotive, The Alco-. Morey.....504–07
Generalized Analogue Computer for Flight Simulation, A. Hall.....308–20
Generator Control Transformer System, Static Accuracy Performance of the Selsyn. Kronacher.....645–53; disc. 653
Generator, Design and Test on Electronic Exciter Supplied from Common Shaft-Driven. Colaiaco, Johnson, Reilly.....328–35; disc. 335
Generator Rating of Induction Motors. Smith.....129–35
Generators as Compared to Conventional Methods, Excitation Improvement—Electronic Excitation and Regulation of Electric. Phillips, Lambert, Pattison.....338–40; disc. 340
Generators at Elevated Gas Pressures, Loading of Hydrogen-Cooled. Snell.....186–99; disc. 199
Generators, Liquid Cooling of A-C Turbine. Part II. Fechheimer.....165–71; disc. 171
(Part I—1947)
Generators, Maximum Short-Circuit Current of D-C Motors and. (Committee Report).....146–9
Generators with Suddenly Applied Loads, Regulation of A-C. Part II. Harder, Cheek, Clayton.....395–405; disc. 405
(Part I—1944)
Gradient Meter, A Voltage. Tremaine, Cheek.....633–7; disc. 637
Graphitizing Furnaces, Electric Equipment and Operation of. Cole.....563–6
Ground Distance Relaying, Combined Phase and. New.....37–42; disc. 42
Ground Protection, Sensitive. (Committee Report).....473–5; disc. 475
Grounding and Testing Device for Metal-Clad Switchgear, A New. Krida, McCurry.407–12; disc. 412
Grounding of Electrical Installations on Customer's Premises, Protective. Schirmer.....657–9

H

Harmonic Index—A Tool for Transformer Audio Noise Investigation. Mutschler, Madden.....115–18; disc. 118
Hazards to Farm Stock, Electrical. Buchanan.....654–6
Hazards, Types, Regulations, and Safe Application, Electric Fences—. Dalziel.....8–15
Heat-Transfer Coefficients for Hydrogen-Cooled Rotating Electric Machines, Surface. Snell, Norris, Buckland.....174–85; disc. 185
Heat Transfer Study on Power Cable Ducts and Duct Assemblies. Greebler, Barnett.....357–64; disc. 364
High-Speed Reclosing on Long and Heavily Loaded Transmission Lines, Consideration of Requirements and Limitations of Relaying and. Parks, Brownlee.....103–07; disc. 107
High-Voltage, High-Capacity Impulse Circuit Breaker, Development and Testing of an Improved. Rietz.....15–25; disc. 25
High-Voltage Oil Circuit Breakers for 5,000,000 to 10,000,000-Kva Interrupting Capacity. Leeds, Friedrich.....70–6; disc. 76
High-Voltage Transmission Lines, Relay Protection for Medium Length. Kinghorn.....461–5; disc. 465
Horsepower Gas-Turbine Electric Locomotive, Control System for a 4,500-. Warrick.....508–13
Horsepower Gas-Turbine Electric Locomotive, The Alco-GE 4,500-. Morey.....504–07
Hydrogen-Cooled Generators at Elevated Gas Pressures Loading of. Snell.....186–99; disc. 199
Hydrogen-Cooled Rotating Electric Machines, Surface Heat-Transfer Coefficients for. Snell, Norris, Buckland.....174–85; disc. 185

I

Ignitron Rectifiers, Control of Large D-C Motors Supplied From. Livingston.....205–10
Improved Luminous Sign Cable, Development of. Roehmann, Greenfield.....350–5; disc. 355
Improved Method of Measuring Dissipation Factor and Dielectric Constant Using the Susceptance Variation Principle, An. Miller, Whelan.....491–7
Improvement—Electronic Excitation and Regulation of Electric Generators as Compared to Conventional Methods, Excitation. Phillips, Lambert, Pattison.....338–40; disc. 340
Improvements in the Characteristics of A-C Lead Networks for Servomechanisms. McDonald.293–300
Improvements in the Performance Calculations of Single-Phase Induction Motors, Suggested. Thacker, Gopalakrishna.....1–6; disc. 6

Impulse Circuit Breaker, Development and Testing of an Improved High-Voltage, High-Capacity. Rietz ..... 15–25; disc. 25
Impulse Measurements by Repeated-Structure Networks. Dawes, Thomas, Drought ..... 571–80; disc. 580
Incremental Losses in Power Transmission Networks Total and. Ward, Eaton, Hale ..626–31; disc. 631
Index—A Tool for Transformer Audio Noise Investigation, Harmonic. Mutschler, Madden ..... 115–18; disc. 118
Inductances of Synchronous Machines, Per-Unit Kirschbaum 231–4
Induction Motors, Generator Rating of. Smith..129–35
Induction Motors, Suggested Improvements in the Performance Calculations of Single-Phase. Thacker, Gopalakrishna ..... 1–6; disc. 6
(Industrial) Basic Patterns for Arrangement of Electric Power Systems for Steel Mills. Finison ..... 54–9; disc. 59
Industry, The Theory of the Current Transductor and Its Application in the Aluminum. Specht, Wagner ..... 441–52; disc. 452
Installations on Customer's Premises, Protective Grounding of Electrical. Schirmer 657–9
Instrument Transformers, A New Dry-Type Insulation for. Pfunitner, Franck, D'Entremont 453–8
Instrumentation and Controls for Steam Electric Power Stations, Centralized. Mallory ..591–6; disc. 596
(Instruments) A Voltage Gradient Meter. Tremaine, Cheek ..... 633–7; disc. 637
(Instruments) Noncontacting Thickness Gauge Using Beta Rays. Clapp, Bernstein 488–90
(Instruments) The Metrotype System of Digital Recording and Telemetering. Foster ..543–6; disc. 546
(Instruments) The Theory of the Current Transductor and Its Application in the Aluminum Industry. Specht, Wagner ..... 441–52; disc. 452
(Insulated Conductors) Development of Improved Luminous Sign Cable. Roehmann, Greenfield ..... 350–5; disc. 355
(Insulated Conductors) Heat Transfer Study on Power Cable Ducts and Duct Assemblies. Greebler, Barnett ..... 357–64; disc. 364
(Insulated Conductors) The Thermal Resistance Between Cables and a Surrounding Pipe or Duct Wall. Buller, Neher ..... 342–7; disc. 347
Insulation for Instrument Transformers, A New Dry-Type. Pfunitner, Franck, D'Entremont 453–8
Insulation Levels, Lightning Arresters as a Criterion for Rorden ..... 84–91; disc. 91
Insulation, Margins Between Lightning Arrester Protective Levels and Transformer. Vogel ..... 110–12; disc. 112
Interrupting Capacity, High-Voltage Oil Circuit Breakers for 5,000,000 to 10,000,00-Kva. Leeds, Friedrich ..... 70–6; disc. 76
Investigation, Harmonic Index—A Tool for Transformer Audio Noise. Mutschler, Madden ..... 115–18; disc. 118
Irradiation of Spark Gaps for Voltage Measurements The. Hardy, Craggs 584–90

J

Joints for High Temperature Operation of Railway Traction Armatures, Solderless Commutator. Reed 638–41

L

(Land Transportation) Control System for a 4,500-Horsepower Gas-Turbine Electric Locomotive. Warrick 508–13
(Land Transportation) Rectifier-Type Motive Power for Railroad Electrification. Hibbard, Whittaker, Ames ..... 519–23; disc. 523
(Land Transportation) Rotating Electric Equipment for a Gas-Turbine Electric Locomotive. Coho..514–18
(Land Transportation) Solderless Commutator Joints for High Temperature Operation of Railway Traction Armatures. Reed 638–41
(Land Transportation) The Alco-GE 4,500 Horsepower Gas-Turbine Electric Locomotive. Morey..504–07
Lead for A-C Servo Systems with Compensation for Carrier Frequency Changes, Phase. Notthoff ..... 285–91; disc. 291
Lead Networks for Servomechanisms, Improvements in the Characteristics of A-C. McDonald 293–300
Levels and Transformer Insulation, Margins Between Lightning Arrester Protective. Vogel ..... 110–12; disc. 112
Levels, Lightning Arresters as a Criterion for Insulation. Rorden ..... 84–91; disc. 91
Lightning Arrester Protective Levels and Transformer Insulation, Margins Between. Vogel ..... 110–12; disc. 112
Lightning Arrester Standard, New. Stewart, Defandorf 525–6
Lightning Arresters as a Criterion for Insulation Levels. Rorden ..... 84–91; disc. 91
Limit, Effect of Buck-Boost Voltage Regulator on Steady-State Power. Concordia ..... 380–4; disc. 384
Limitations of Relaying and High-Speed Reclosing on Long and Heavily Loaded Transmission Lines, Consideration of Requirements and. Parks, Brownlee ..... 103–07; disc. 107
Line Protection of Short Lines of the Metropolitan Area of a Typical System, Transmission-. Marter ..... 468–71; disc. 471
Lines, Consideration of Requirements and Limitations of Relaying and High-Speed Reclosing on Long and Heavily Loaded Transmission. Parks, Brownlee ..... 103–07; disc. 107
Lines, Relay Protection for Medium Length High-Voltage Transmission. Kinghorn ....461–5; disc. 465
Liquid Cooling of A-C Turbine Generators. Part II. Fechheimer ..... 165–71; disc. 171
(Part I—1947)
Load for Testing Rectifiers, Synthetic. Tetherow ..642–4
Loading of Hydrogen-Cooled Generators at Elevated Gas Pressures. Snell ..... 186–99; disc. 199
Loads, Regulation of A-C Generators with Suddenly Applied. Part II. Harder, Check, Clayton ..... 395–405; disc. 405
(Part I—1944)
Locomotive, Control System for a 4,500-Horsepower Gas-Turbine Electric. Warrick 508–13
Locomotive, Rotating Electric Equipment for a Gas-Turbine Electric. Coho 514–18
Locomotive, The Alco-GE 4,500-Horsepower Gas-Turbine Electric. Morey 504–07
Locus Method, Control System Synthesis by Root. Evans 66–9
Losses in Power Transmission Networks, Total and Incremental. Ward, Eaton, Hale..626–31; disc. 631
Luminous Sign Cable, Development of Improved Roehmann, Greenfield ..... 350–5; disc. 355

M

Machines and Their Application, Spring and Damping Coefficients of Synchronous. Kilgore, Whitney ..... 226–9; disc. 229
Machines, Per-Unit Inductances of Synchronous. Kirschbaum 231–4
Machines, Potier Reactance for Salient-Pole Synchronous. Mikhail 235–8
Machines, Surface Heat-Transfer Coefficients for Hydrogen-Cooled Rotating Electric. Snell, Norris, Buckland ..... 174–85; disc. 185
Magnetic Amplifier Frequency Control, A. Johnson, Schafer 613–15
Magnetic Amplifiers, An Analysis of Transients and Feedback in. Johnson, Latson ..604–11; disc. 611
Magnetic Amplifiers, An Analysis of Transients in. Ver Planck, Finzi, Beaumariage 498–503
Magnetic-Fluid Clutch Servomechanisms, Characteristics of Some. Parziale, Tilton 150–7
Margins Between Lightning Arrester Protective Levels and Transformer Insulation. Vogel ..... 110–12; disc. 112
Maximum Short-Circuit Current of D-C Motors and Generators. (Committee Report) 146–9
Measurement of Bandwidth, The Direct. Ammerman 27–31
Measurement, The Irradiation of Spark Gaps for Voltage. Hardy, Craggs 584–90
Measurements by Repeated Structure Networks, Impulse. Dawes, Thomas, Drought..571–80; disc. 580
Measuring Dissipation Factor and Dielectric Constant Using the Susceptance Variation Principle, An Improved Method of. Miller, Whelan 491–7
Measuring the Ratio and Phase Angle of Current Transformers, A Primary Method of. Brownlee..459–60
Mechanisms, Electrode Control and Associated Operating. Hanff ..... 567–70; disc. 570
Message Accounting System, Fundamentals of the Automatic Telephone. Meszar..255–68; disc. 269

Surface Heat-Transfer Coefficients for Hydrogen-Cooled Rotating Electric Machines. Snell, Norris, Buckland....174–85; disc. 185
Surge Protection of Cable-Connected Equipment. Witzke, Bliss....527–38; disc. 539
Survey of Bushing-Type Current Transformers for Metering Purposes, A. Camilli....429–40
Switchgear, A New Grounding and Testing Device for Metal-Clad. Krida, McCurry...407–12; disc. 412
(Switchgear) A New 69-Kv Oil Blast Circuit Breaker. Rietz, Balentine....416–23; disc. 423
(Switchgear) Development and Testing of an Improved High-Voltage, High-Capacity Impulse Circuit Breaker. Rietz....15–25; disc. 25
Switching System, The Number 5 Crossbar Dial Telephone. Korn, Ferguson....244–54
Synchronous Machines and Their Application, Spring and Damping Coefficients of. Kilgore, Whitney....226–9; disc. 229
Synchronous Machines, Per-Unit Inductances of Kirchbaum....231–4
Synchronous Machines, Potier Reactance for Salient-Pole. Mikhail....235–8
Synthesis by Root Locus Method, Control System. Evans....66–9
Synthesizing Contactor Servomechanisms, A Frequency Response Method for Analysing and. Kochenburger....270–83; disc. 283
Synthetic Load for Testing Rectifiers. Tetherow..642–4
System, Bus Transfer Tests on 2,300-Volt Station Auxiliary. Johnson, Thompson....386–90; disc. 390
System for a 4,500-Horsepower Gas-Turbine Electric Locomotive, Control. Warrick....508–13
System for Short Submarine Cables, A Two-Channel Carrier Telegraph. Newell, Cramer....61–5
System, Fundamentals of the Automatic Telephone Message Accounting. Mestar...255–68; disc. 269
System of Digital Recording and Telemetering, The Metrotype. Foster....543–6; disc. 546

System Performance with Motor-Driven Exciters, Excitation. Mellor, Temoshok.....321–7
System, Static Accuracy Performance of the Selsyn Generator Control Transformer. Kronacher.....645–53; disc. 653
System Synthesis by Root Locus Method, Control. Evans.....66–9
System, The Number 5 Crossbar Dial Telephone Switching. Korn, Ferguson.....244–54
Systems for Steel Mills, Basic Patterns for Arrangement of Electric Power. Finison.....54–9; disc. 59
Systems with Compensation for Carrier Frequency Changes, Phase Lead for A-C Servo. Nothhoff.....285–91; disc. 291

T

Tables, Basic Theory Underlying Bell System Facilities Capacity. Gracey.....238–43; disc. 243
Tape-to-Page Translator, A Printing Telegraph. Frost.....79–83
Techniques on the Anacom—Electric Analog Computer, New. Harder, Carleton.....547–56
Telemetering, The Metrotype System of Digital Recording and. Foster.....543–6; disc. 546
Telegraph Regenerative Receiver, A New Electronic. Ostendorf.....32–6; disc. 36
Telegraph System for Short Submarine Cables, A Two-Channel Carrier. Newell, Cramer.....61–5
Telegraph Tape-to-Page Translator, A Printing. Frost.....79–83
Telephone Message Accounting System, Fundamentals of the Automatic. Meszar.....255–68; disc. 269
Telephone Switching System, The Number 5 Crossbar Dial. Korn, Ferguson.....244–54
(Televison) Clampers in Video Transmission. Doba, Rieke.....477–87
Temperature Operation of Railway Traction Armatures, Solderless Commutator Joints for High. Reed.....638–41
Test on Electronic Exciter Supplied from Common Shaft-Driven Generator, Design and. Colaiaco, Johnson, Reilly.....328–35; disc. 335
Testing Device for Metal-Clad Switchgear, A New Grounding and. Krida, McCurry..407–12; disc. 412
Testing of an Improved High-Voltage, High-Capacity Impulse Circuit Breaker, Development and. Rietz.....15–25; disc. 25
Testing on Large D-C Apparatus, Quick and Accurate Production. Baldwin, Barnhart.....136–8
Testing Rectifiers, Synthetic Load for. Tetherow..642–4
Tests on 2,300-Volt Station Auxiliary System, Bus Transfer. Johnson, Thompson...386–90; disc. 390
Theory of the Current Transductor and Its Application in the Aluminum Industry, The. Specht, Wagner.....441–52; disc. 452
Theory Underlying Bell System Facilities Capacity Tables, Basic. Gracey.....238–43; disc. 243
Thermal Resistance Between Cables and a Surrounding Pipe or Duct Wall, The. Buller, Neher.....342–7; disc. 347
Thickness Gauge Using Beta Rays, Noncontacting. Clapp, Bernstein.....488–90
Thyratron Deionization Time, Statistical Nature and Physical Concepts of. Romanowitz, Dow..368–79
Time, Statistical Nature and Physical Concepts of Thyratron Deionization. Romanowitz, Dow.....368–79
Tool for Transformer Audio Noise Investigation, Harmonic Index—A. Mutschler, Madden.....115–18; disc. 118
Total and Incremental Losses in Power Transmission Networks. Ward, Eaton, Hale..626–31; disc. 631
Traction Armatures, Solderless Commutator Joints for High Temperature Operation of Railway. Reed.....638–41
Transductor and Its Application in the Aluminum Industry, The Theory of the Current. Specht, Wagner.....441–52; disc. 452
Transfer Coefficients for Hydrogen-Cooled Rotating Electric Machines, Surface Heat-. Snell, Norris, Buckland.....174–85; disc. 185
Transfer Study on Power Cable Ducts and Duct Assemblies, Heat. Greebler, Barnett..357–64; disc. 364
Transfer Tests on 2,300-Volt Station Auxiliary System, Bus. Johnson, Thompson.....386–90; disc. 390
Transformer Audio Noise Investigation, Harmonic Index—A Tool for. Mutschler, Madden.....115–18; disc. 118
Transformer Insulation, Margins Between Lightning Arrester Protective Levels and. Vogel.....110–12; disc. 112
Transformer System, Static Accuracy Performance of the Selsyn Generator Control. Kronacher.....645–53; disc. 653
Transformers, A New Dry-Type Insulation for Instrument. Plunniner, Franck, D'Entremont.....453–8
Transformers, A New Line of Orthomagnetic Bushing-Type Current. Farr.....424–8
Transformers, A Primary Method of Measuring the Ratio and Phase Angle of Current. Brownlee.....459–60
Transformers, Audible Noise of Power. Gordy.....45–50; disc. 50
Transformers for Metering Purposes, A Survey of Bushing-Type Current. Camilli.....429–40
Transformers in Residential and Commercial Areas, Audio Noise in. Baugh.....121–6; disc. 126
Transformers on the System of the Bonneville Power Administration, Application and Handling of Very Large Power. Stevens.....158–63; disc. 163
Transient Response of Direct-Current Dynamos. Koenig.....139–44; disc. 144
Transients and Feedback in Magnetic Amplifiers, An Analysis of. Johnson, Latson....604–11; disc. 611
Transients in Magnetic Amplifiers, An Analysis of. VerPlanck, Finzi, Beaumariage.....498–503
Translator, A Printing Telegraph Tape-to-Page. Frost.....79–83
Transmission, Clampers in Video. Doba, Rieke..477–87
(Transmission) Dielectric-Recovery Characteristics of Power Arcs in Large Air Gaps. McCann, Conner, Ellis.....616–24; disc. 624
Transmission-Line Protection of Short Lines of the Metropolitan Area of a Typical System. Marter.....468–71; disc. 471
Transmission Lines, Consideration of Requirements and Limitations of Relaying and High-Speed Reclosing on Long and Heavily Loaded. Parks, Brownlee.....103–07; disc. 107
Transmission Lines, Relay Protection for Medium Length High-Voltage. Kinghorn..461–5; disc. 465
Transmission Networks, Total and Incremental Losses in Power. Ward, Eaton, Hale...626–31; disc. 631
Turbine Electric Locomotive, Control System for a 4,500-Horsepower Gas-. Warrick.....508–13
Turbine Electric Locomotive, Rotating Electric Equipment for a Gas-. Coho.....514–18
Turbine Electric Locomotive, The Alco-GE 4,500-Horsepower Gas-. Morey.....504–07
Turbine Generators, Liquid Cooling of A-C. Part II. Fechheimer.....165–71; disc. 171 (Part I—1947).
Two-Channel Carrier Telegraph System for Short Submarine Cables, A. Newell, Cramer.....61–5

V

Variation Principle, An Improved Method of Measuring Dissipation Factor and Dielectric Constant Using the Susceptance. Miller, Whelan.....491–7
Video Transmission, Clampers in. Doba, Rieke..477–87
Voltage Gradient Meter, A. Tremaine, Cheek.....633–7; disc. 637
Voltage Measurement, The Irradiation of Spark Gaps for. Hardy, Craggs.....584–90
Voltage Regulator on Steady-State Power Limit, Effect of Buck-Boost. Concordia....380–4; disc. 384

W

Wall, The Thermal Resistance Between Cables and a Surrounding Pipe or Duct. Buller, Neher.....342–7; disc. 347

Preface

The 1950 TRANSACTIONS (volume 69) of the American Institute of Electrical Engineers is published in two parts. Part I contains technical program papers and related discussions presented at the Winter General Meeting, New York, N. Y., January 30–February 3, 1950.

Part II of the 1950 volume contains approved papers and related discussions presented at the following meetings:

North Eastern District Meeting, Providence, R. I., April 26–28, 1950.
Great Lakes District Meeting, Jackson, Mich., May 11–12, 1950.
Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950.
Middle Eastern District Meeting, Baltimore, Md., October 3–5, 1950.
Fall General Meeting, Oklahoma City, Okla., October 23–27, 1950.

Part I of Volume 69 contained an index covering only the first half of the year. A complete multi-entry index for 1950 (Parts I and II) is included in this volume beginning on page 1737. The Report of the Board of Directors and the list of Officers and Committees for 1950–1951 also are included in Part II.

The original number assigned each paper by the Technical Program Committee is given in the author index.

Statements and opinions given in papers and discussions published in TRANSACTIONS are the expressions of contributors for which the American Institute of Electrical Engineers assumes no responsibility.

Analysis of Synchronous Machine Short Circuits

ROBERT D. CAMBURN
ASSOCIATE AIEE

ERIC T. B. GROSS
FELLOW AIEE

Synopsis: Representation has been made of synchronous machines and power systems by α-, β-, and 0-networks which are basic for the analysis of various types of short circuits. New expressions for the characteristic synchronous machine reactances in α-, β-, 0-components, or Clarke components, are derived. It is found that these characteristic reactances are constant so that the use of Clarke component networks does not compare unfavorably with other methods of short-circuit analysis.

IN RECENT years a number of papers have been published[1,2,3] dealing with a new type of substituted variables to supplement symmetrical components. These new components are α-, β-, and 0-components or "Clarke components" as they will be called here following a suggestion which was discussed at some length before a meeting of the AIEE.[4]

α-components are equal in phases b and c; they are there opposite in sign and half the magnitude of the α-component in phase a.

β-components are equal in phases b and c but of opposite sign; in phase a they are zero.

0-components are equal in all three phases.

Current components of this nature were first used in 1917 by W. W. Lewis[5] for the analysis of short circuits occurring on the high-voltage side of a delta-Y transformer. Figure 1(A) shows that a line-to-line fault on the Y-side of a delta-Y transformer causes β-currents in the Y-connected windings and α-currents in the leads to the delta-connected windings. From Figure 1(B) it can be seen that a line-to-neutral fault on the wye side of a delta-Y transformer causes α and 0-currents in the Y-connected windings, and β-currents in the leads to the delta-connected windings. A third condition which results in a flow of Clarke component-type currents, is the line-to-line fault as shown in Figure 1(C). In his discussion, however, Lewis made no attempt to establish a system of components which could be generally applied to the analysis of unbalanced 3-phase circuits.

Edith Clarke was the first to present a complete definition of these components and to describe their usefulness in the solution of system engineering problems. Later, E. W. Kimbark[3] presented a paper on the applications of "2-phase co-ordinates," a slightly modified form of Edith Clarke's α-, β-, and 0-components. These two papers[1,2] and the discussions[4] contain the basic material on Clarke components, though the same or similar components have been used by others in the solution of special problems.[3,4]

Clarke components can be used in the analysis of any unbalanced 3-phase circuits, however, their application is presently limited because the well-established symmetrical components may be used with equal or perhaps greater facility in many cases. Clarke components allow a more direct solution where any of the unbalances sketched in Figure 1 are involved. They can be used in the system recovery voltage determination by transient analyzer methods when symmetrical components are not applicable, as will be shown in a paper in preparation.

It is the purpose of this paper to derive new expressions for synchronous machine reactances in Clarke components. In the same manner as symmetrical component analysis is undertaken, Clarke component networks representative of a synchronous machine will be developed, and methods of using these networks to solve for the various types of short-circuit currents and voltages will be indicated. Of particular interest is the analysis of generator reactances when a line-to-line fault occurs on the high-voltage side of a Y-delta transformer (the generator being connected to the delta side) as this does not seem to be contained in known references.

An underlying motive for undertaking this analysis was the belief that Clarke component currents have a direct physical significance from the standpoint of synchronous machinery. It was expected that Clarke component analysis would not involve varying impedances (that is to say, varying with the type of unbalanced faults) such as negative sequence generator impedance.[10] The results of this investigation seem to indicate this advantage of Clarke components.

The reasoning behind these presumptions may be indicated by considering an idealized synchronous machine. In Figure 2, it is shown that α-current magnetizes only the vertical or "α"-axis of the stator. In Figure 3, it is shown that β-current magnetizes only the horizontal or "β"-axis. Thus, the problem of analyzing a 3-phase machine by means of Clarke components is equivalent to the analysis of a 2-phase machine with stator windings in quadrature. The faults shown in Figure 1 would each be short circuits on only one of the two phase windings.

As is done in symmetrical component analysis, the machine will be represented by component networks consisting of driving voltages and internal impedances which may be interconnected to solve for various types of short circuits. In de-

Paper 50-37, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950, and at the North Eastern District Meeting, Providence, R. I., April 26–28, 1950. Manuscript submitted March 21, 1949; made available for printing December 22, 1949.

ROBERT D. CAMBURN is with Commonwealth Services, Inc., Jackson, Mich., and ERIC T. B. GROSS is with Illinois Institute of Technology, Chicago, Ill.

Figure 1. Distribution of Clarke component currents under fault conditions

(A) Line-to-line fault on high-voltage system. (B) Line-to-ground fault on high-voltage system. (C) Line-to-line fault on generator leads

riving component impedance expressions R. H. Park's analysis[6,7] of the two reactances theory of synchronous machines is applied. However, a slightly modified treatment of Park's work, following W. A. Lewis,[8] is used. It is assumed here that the quadrature axis is 90 degrees behind the direct axis so that $I_a = I_q + jI_d$. In Park's papers, the quadrature axis is defined to be 90 degrees ahead of the direct axis.

Fundamental Relationships

The relations between Clarke components phase currents and voltages are defined as follows:

$$I_a = I_\alpha + I_0$$

$$I_b = -\frac{1}{2}I_\alpha + \frac{\sqrt{3}}{2}I_\beta + I_0$$

$$I_c = -\frac{1}{2}I_\alpha - \frac{\sqrt{3}}{2}I_\beta + I_0$$

$$V_a = V_\alpha + V_0$$

$$V_b = -\frac{1}{2}V_\alpha + \frac{\sqrt{3}}{2}V_\beta + V_0$$

$$V_c = -\frac{1}{2}V_\alpha - \frac{\sqrt{3}}{2}V_\beta + V_0 \qquad (1)$$

$$I_\alpha = \frac{2}{3}\left(I_a - \frac{I_b + I_c}{2}\right)$$

$$I_\beta = \frac{1}{\sqrt{3}}(I_b - I_c)$$

$$I_0 = \frac{1}{3}(I_a + I_b + I_c)$$

$$V_\alpha = \frac{2}{3}\left(V_a - \frac{V_b + V_c}{2}\right)$$

$$V_\beta = \frac{1}{\sqrt{3}}(V_b - V_c)$$

$$V_0 = \frac{1}{3}(V_a + V_b + V_c) \qquad (2)$$

Symbols in the equations may be interpreted either as phasor, or as instantaneous quantities. Modified networks having twice the usual zero sequence currents and one-half zero sequence impedance are employed to simplify the analysis of some types of short circuit.

The General Component Network

For purposes of calculation, the synchronous machine is usually pictured as an internal electromotive force in series with an impedance network. Similarly, the Clarke component networks representative of a synchronous machine are composed of electromotive forces and some network of impedances. Figure 4 shows such circuit of the most general nature having all possible combinations of self and mutual impedance. The voltage E_α, E_β, and E_0 at the left in the figure are component electromotive forces (driving voltages). At the right, V_α, V_β, and V_0 are component terminal voltages.

Writing circuit equations for this network gives

$$\begin{aligned} E_\alpha - V_\alpha &= I_\alpha Z_{\alpha\alpha} + I_\beta Z_{\alpha\beta} + I_0 Z_{\alpha 0} \\ E_\beta - V_\beta &= I_\alpha Z_{\beta\alpha} + I_\beta Z_{\beta\beta} + I_0 Z_{\beta 0} \\ E_0 - V_0 &= I_\alpha Z_{0\alpha} + I_\beta Z_{0\beta} + I_0 Z_{00} \end{aligned} \qquad (3)$$

It is then necessary to determine the independent variables in equation 3, the driving voltages and the various impedances.

Figure 2 (left). Flux produced in the machine by α-currents

$$\Lambda_\alpha = NI_a + 2\frac{1}{4}NI_a = \frac{3}{2}NI_\alpha$$

$$\Lambda_\beta = 0$$

Figure 3 (right). Flux produced in the machine by β-currents

$$\Lambda_\alpha = 0$$

$$\Lambda_\beta = 2\frac{\sqrt{3}}{2}NI_b = \sqrt{3}NI_b = \frac{3}{2}NI_\beta$$

Figure 4. General Clarke component network for the representation of a synchronous machine

Components of Generated Electromotive Force

Since only balanced 3-phase voltages are generated in the machine, the internal voltages may be found at once from equation 2. That is, since

$$E_a = E_a e^{j0}$$

$$E_b = E_a e^{j\frac{4\pi}{3}}$$

$$E_c = E_a e^{j\frac{2\pi}{3}} \qquad (4)$$

we have

$$E_\alpha = \frac{2}{3}\left(E_a - \frac{E_b + E_c}{2}\right) = E_a$$

$$E_\beta = \frac{1}{\sqrt{3}}(E_b - E_c) = -jE_a$$

$$E_0 = \frac{1}{3}(E_a + E_b + E_c) = 0 \qquad (5)$$

Component Network Impedances

The component impedances for the network shown in Figure 4 can be found analytically by assuming certain currents to be circulated by an external source, while the field is open or short circuited and the machine driven at synchronous speed. Under actual test, reactances measured with the field open circuited would be synchronous reactances. With the field short circuited, the result would be transient reactance. Further, if the effect of a damper winding were included, the result would be subtransient reactance. Here, the distinction will not be evident, and so the symbol X_d may be interpreted as any of the three.

Since there now is no generated electromotive force, equation 3 becomes

$$\begin{aligned} -V_\alpha &= -I_\alpha Z_{\alpha\alpha} - I_\beta Z_{\alpha\beta} - I_0 Z_{\alpha 0} \\ -V_\beta &= -I_\alpha Z_{\beta\alpha} - I_\beta Z_{\beta\beta} - I_0 Z_{\beta 0} \\ -V_0 &= -I_\alpha Z_{0\alpha} - I_\beta Z_{0\beta} - I_0 Z_{00} \end{aligned} \qquad (6)$$

By comparison of the derived expressions for component terminal voltages with equation 6, the component impedances may be determined.

Figure 5. Clarke component networks for the analysis of 3-phase fault

(A) Single-line diagram. (B) Clarke component networks. jX_e is a reactance external to the generator

Component terminal voltages now can be found in the following way:

1. Define the currents to be circulated in the generator leads and transform them into direct and quadrature axis currents.

Since the quadrature axis is defined to lag the direct axis by 90 degrees, the rotation of positive field flux in the direct axis generates a positive voltage in the quadrature axis, or, $E_q=\omega\Lambda_d=E_t$. It is convenient to choose the quadrature axis voltage as the reference to give $\mathbf{E}_a=E_q+jE_d=E_t+j0$ at no load. Then $\mathbf{I}_a=I_q+jI_d$.

The expressions for instantaneous direct and quadrature axis, and zero sequence currents are[9]

$$i_d=\frac{2}{3}\left[i_a\cos\sigma+i_b\cos\left(\sigma-\frac{2\pi}{3}\right)+i_c\cos\left(\sigma-\frac{4\pi}{3}\right)\right]$$

$$i_q=\frac{2}{3}\left[i_a\sin\sigma+i_b\sin\left(\sigma-\frac{2\pi}{3}\right)+i_c\sin\left(\sigma-\frac{4\pi}{3}\right)\right]$$

$$i_0=\frac{1}{3}[i_a+i_b+i_c] \tag{7}$$

where σ is the electrical angle between the axis of phase a and the direct axis. Then $\sigma=\omega t+\sigma_0$, where σ_0 is the rotor position at $t=0$.

2. Find the flux linkages of the direct, quadrature, and zero windings. There is no field current so that the flux linking each coil is self induced.

Thus

$$\Lambda_d=L_d i_d$$
$$\Lambda_q=L_q i_q$$
$$\Lambda_0=L_0 i_0 \tag{8}$$

L_d, L_q, L_0 are the direct axis, quadrature axis, and zero sequence inductances of the machine found directly from test data.

3. Differentiate and add the flux linkages to find direct axis, quadrature axis, and zero sequence voltages. The equations for these voltages are

$$v_d=\frac{d\Lambda_d}{dt}+\Lambda_q\frac{d\sigma}{dt}$$
$$v_q=\frac{d\Lambda_q}{dt}-\Lambda_d\frac{d\sigma}{dt}$$
$$v_0=\frac{d\Lambda_0}{dt} \tag{9}$$

The armature resistance is neglected as is common practice in short-circuit analysis of synchronous machines.

4. Transform the voltages in equation 9 into phase voltages, and then into Clarke components. It is shown in reference 9 that

$$v_a=v_d\cos\sigma+v_q\sin\sigma+v_0$$
$$v_b=v_d\cos\left(\sigma-\frac{2\pi}{3}\right)+v_q\sin\left(\sigma-\frac{2\pi}{3}\right)+v_0$$
$$v_c=v_d\cos\left(\sigma-\frac{4\pi}{3}\right)+v_q\sin\left(\sigma-\frac{4\pi}{3}\right)+v_0 \tag{10}$$

By substituting these voltage expressions in equation 2, it will be found that

$$v_\alpha=\frac{2}{3}\left\{v_d\left[\cos\sigma-\frac{1}{2}\cos\left(\sigma-\frac{2\pi}{3}\right)-\frac{1}{2}\cos\left(\sigma-\frac{4\pi}{3}\right)\right]+v_q\left[\sin\sigma-\frac{1}{2}\sin\left(\sigma-\frac{2\pi}{3}\right)-\frac{1}{2}\sin\left(\sigma-\frac{4\pi}{3}\right)\right]\right\}=v_d\cos\sigma+v_q\sin\sigma$$

$$v_\beta=\frac{1}{3}\left\{v_d\left[\cos\left(\sigma-\frac{2\pi}{3}\right)-\cos\left(\sigma-\frac{4\pi}{3}\right)\right]+v_q\left[\sin\left(\sigma-\frac{2\pi}{3}\right)-\sin\left(\sigma-\frac{4\pi}{3}\right)\right]\right\}=v_d\sin\sigma-v_q\cos\sigma$$

$$v_0=v_0 \tag{11}$$

It then is necessary to circulate currents in the windings similar to the various types of fault current which might occur and carry out the procedure outlined to find the component terminal voltages. The resulting expressions will be compared with equations 6 to determine the character of the Clarke component impedances.

Clarke Component Impedance Networks

For each type of short circuit which seems to be of major practical importance from the standpoint of network analysis, the nature of the Clarke component impedances will be analyzed and methods of solution for short circuit currents and voltages indicated.

The 3-Phase Fault

To analyze the component impedances for a 3-phase fault, balanced 3-phase currents must be circulated in the machine. Let

$$i_a=\sqrt{2}I\sin(\sigma+\phi)$$
$$i_b=\sqrt{2}I\sin\left(\sigma+\phi-\frac{2\pi}{3}\right)$$
$$i_c=\sqrt{2}I\sin\left(\sigma+\phi-\frac{4\pi}{3}\right) \tag{12}$$

By substituting these currents in equations 7, it is found that

$$i_d=\sqrt{2}I\sin\phi$$
$$i_q=\sqrt{2}I\cos\phi$$
$$i_0=0 \tag{13}$$

Then, from equations 8

$$\Lambda_d=L_d i_d=L_d\sqrt{2}I\sin\phi$$
$$\Lambda_q=L_q i_q=L_q\sqrt{2}I\cos\phi$$
$$\Lambda_0=0 \tag{14}$$

From equations 9, the direct and quadrature axis voltages are

$$v_d=\frac{d\Lambda_d}{dt}+\Lambda_q\frac{d\sigma}{dt}=\omega L_q\sqrt{2}I\cos\phi$$
$$v_q=\frac{d\Lambda_q}{dt}-\Lambda_d\frac{d\sigma}{dt}=-\omega L_d\sqrt{2}I\sin\phi$$
$$v_0=\frac{d\Lambda_0}{dt}=0 \tag{15}$$

since $\sigma=\omega t+\sigma_0$ and, therefore, $d\sigma/dt=\omega=2\pi f$. The quantities ωL_d and ωL_q are the direct and quadrature axis reactances of the machine X_d and X_q.

From equations 11, the voltages in equations 15 may be transformed into Clarke component voltages. Thus

Figure 6. Clarke component networks for the analysis of line-to-line fault on generator terminals

(A) 3-phase circuits. (B) Component networks

$$v_\alpha = X_q\sqrt{2}I\cos\phi\cos\sigma - X_d\sqrt{2}I\sin\phi\sin\sigma$$
$$v_\beta = X_q\sqrt{2}I\cos\phi\sin\sigma + X_d\sqrt{2}I\sin\phi\cos\sigma$$
$$v_0 = 0 \tag{16}$$

In short circuit analysis, it is usually assumed that the fault current lags the driving voltage by $\pi/2$, that is, the impedance between the generated electromotive force and the fault is entirely reactive. Internal electromotive force of the generator may be written $E_a = \sqrt{2}E\sin\sigma$. The fault current in phase a will then be $i_a = \sqrt{2}I\sin(\sigma - \pi/2)$, or, $\phi = -\pi/2$.

Equations 16 become, upon setting ϕ equal to $-\pi/2$

$$v_\alpha = X_d\sqrt{2}I\sin\sigma$$
$$v_\beta = -X_d\sqrt{2}I\cos\sigma$$
$$v_0 = 0 \tag{17}$$

Transforming the assumed currents in equations 12 into Clarke components gives

$$i_\alpha = -\sqrt{2}I\cos\sigma$$
$$i_\beta = -\sqrt{2}I\sin\sigma$$
$$i_0 = 0 \tag{18}$$

again assuming $\phi = -\pi/2$

Substitutions are made from equations 18 into equations 17 to find

$$v_\alpha = -i_\beta X_d$$
$$v_\beta = i_\alpha X_d$$
$$v_0 = 0 \tag{19}$$

or, in phasor form

$$V_\alpha = -I_\beta X_d$$
$$V_\beta = I_\alpha X_d$$
$$V_0 = 0 \tag{20}$$

Equations 20 may be rewritten, using the fact that for balanced 3-phase currents $I_\alpha = jI_\beta = I_a$, to find

$$V_\alpha = jI_\alpha X_d$$
$$V_\beta = jI_\beta X_d$$
$$V_0 = 0 \tag{21}$$

By comparison of equations 21 with equations 6 for the general component network, it is seen that

$$Z_{\alpha\alpha} = Z_{\beta\beta} = jX_d$$
$$Z_{\alpha\beta} = Z_{\beta\alpha} = 0$$
$$Z_{\alpha 0} = Z_{\beta 0} = 0 \tag{22}$$

The α- and β-network impedances are both direct axis reactances and no mutual impedances between networks are involved.

The Clarke component networks for the solution of this case are shown in Figure 5. Note that it is necessary to solve only one component network. The α-network current is the fault current in phase a.

Line-to-Line Fault on Generator Terminals; Line-to-Ground Fault Beyond a Delta-Y Transformer with Grounded Neutral

A line-to-line fault on the generator terminals or a line-to-ground fault behind a delta-Y transformer (with grounded neutral) will cause β-currents in the generator as shown in Figures 6 and 7.

To derive the component impedances, β-currents will be circulated in the machine. Then

$$i_a = 0$$
$$i_b = \sqrt{2}I\sin(\sigma+\phi)$$
$$i_c = -\sqrt{2}I\sin(\sigma+\phi) \tag{23}$$

Transforming these currents into direct and quadrature axis currents by equations 6 gives

$$i_d = \frac{2}{3}\sqrt{2}I\sin(\sigma+\phi)\left[\cos\left(\sigma - \frac{2\pi}{3}\right) - \cos\left(\sigma - \frac{4\pi}{3}\right)\right] = \frac{\sqrt{2}}{\sqrt{3}}I\,[\cos\phi - \cos(2\sigma+\phi)]$$

$$i_q = \frac{2}{3}\sqrt{2}I\sin(\sigma+\phi)\left[\sin\left(\sigma - \frac{2\pi}{3}\right) - \sin\left(\sigma - \frac{4\pi}{3}\right)\right] = \frac{\sqrt{2}}{\sqrt{3}}I\,[\sin\phi + \sin(2\sigma+\phi)]$$

$$i_0 = 0 \tag{24}$$

The flux linkages are found and differentiated as before to find

$$v_d = \frac{2X_d - X_q}{\sqrt{3}}\sqrt{2}I\sin(2\sigma+\phi) - \frac{X_q}{\sqrt{3}}\sqrt{2}I\sin\phi$$

$$v_q = \frac{X_d - 2X_q}{\sqrt{3}}\sqrt{2}I\cos(2\sigma+\phi) - \frac{X_d}{\sqrt{3}}\sqrt{2}I\cos\phi$$

$$v_0 = 0 \tag{25}$$

Converting these to Clarke component voltages by equations 10 gives

$$v_\alpha = \frac{2X_d - X_q}{2\sqrt{3}}\sqrt{2}I[\sin(3\sigma+\phi) + \sin(\sigma+\phi)] - \frac{X_q}{\sqrt{3}}\sqrt{2}I\cos\sigma\sin\phi + \frac{X_d - 2X_q}{2\sqrt{3}}\sqrt{2}I\,[\sin(3\sigma+\phi) - \sin(\sigma+\phi)] - \frac{X_d}{\sqrt{3}}\sqrt{2}I\sin\sigma\cos\phi$$

$$v_\beta = \frac{2X_d - X_q}{2\sqrt{3}}\sqrt{2}I\,[\cos(\sigma+\phi) - \cos(3\sigma+\phi)] - \frac{X_q}{\sqrt{3}}\sqrt{2}I\sin\sigma\sin\phi - \frac{X_d - 2X_q}{2\sqrt{3}}\sqrt{2}I\,[\cos(\sigma+\phi) + \cos(3\sigma+\phi)] + \frac{X_d}{3}\sqrt{2}I\cos\sigma\cos\phi$$

$$v_0 = 0 \tag{26}$$

The driving voltage behind a line-to-line fault is E_{bc} which lags the voltage in phase a by 90 degrees. If it is assumed, as before, that the fault current lags the driving voltage by 90 degrees, the fault current may be written

$$i_b = \sqrt{2}I\sin\left(\sigma - \frac{\pi}{2} - \frac{\pi}{2}\right), \text{ or, } \phi = -\pi$$

Since only the fundamental frequency components in equations 26 are of interest, the third harmonic terms will be dropped.

Equations 26 may be written

$$v_\alpha = \frac{X_d - X_q}{2\sqrt{3}}\sqrt{2}I\sin\sigma$$

$$v_\beta = \frac{3X_d + X_q}{2\sqrt{3}}\sqrt{2}I\cos\sigma$$

$$v_0 = 0 \tag{27}$$

Converting the assumed currents to component form gives

$$i_\alpha = 0$$

$$i_\beta = \frac{2}{\sqrt{3}}i_b = -\frac{2\sqrt{2}}{\sqrt{3}}I\sin\sigma$$

$$i_0 = 0 \tag{28}$$

Eliminating the α- and 0-component current terms, the general equations 6 become

$$V_\alpha = I_\beta Z_{\alpha\beta}$$
$$V_\beta = I_\beta Z_{\beta\beta}$$
$$V_0 = I_\beta Z_{0\beta} \tag{29}$$

By changing equations 27 and 28 to phasor form and substituting them in equations 29, it will be found that

$$\frac{X_d - X_q}{2\sqrt{3}}I = -\frac{2}{\sqrt{3}}IZ_{\alpha\beta}$$

$$-j\frac{3X_d + X_q}{2\sqrt{3}}I = -\frac{2}{\sqrt{3}}IZ_{\beta\beta}$$

$$0 = -\frac{2}{\sqrt{3}}IZ_{0\beta} \tag{30}$$

Thus, it is seen that

$$Z_{\alpha\beta} = -\frac{X_d - X_q}{4}$$

$$Z_{\beta\beta} = j\frac{3X_d + X_q}{4}$$

$$Z_{0\beta} = 0 \tag{31}$$

Figure 6 shows the component network for the analysis of a line-to-line fault on the generator terminals. It is necessary to solve only one network for current distribution since there is no α-current. The voltages induced in the α-network by β-current flow may be easily calculated after an analysis of the β network is completed. The induced voltage will be in phase with the β current since $Z_{\alpha\beta}$ is a resistance.

Figure 7 shows the component network for the analysis of a line-to-ground

short circuit beyond a delta-Y transformer with grounded neutral. The representation of the transformer is discussed in Appendix II.

Line-to-Line Fault beyond a Delta-Y Transformer

A line-to-line fault beyond a delta-Y transformer causes α-currents to flow in the generator as shown in Figure 8. The currents to be circulated to analyze the impedances are written

$$i_a=\sqrt{2}I\sin(\sigma+\phi)$$

$$i_b=i_c=-\frac{\sqrt{2}}{2}I\sin(\sigma+\phi) \tag{32}$$

The direct and quadrature axis currents are found to be

$$i_d=\frac{\sqrt{2}}{2}I\,[\sin\phi+\sin(2\sigma+\phi)]$$

$$i_q=\frac{\sqrt{2}}{2}I\,[\cos\phi-\cos(2\sigma+\phi)]$$

$$i_0=0 \tag{33}$$

The flux linkages of the direct and quadrature axis windings are found and differentiated as before to find

$$v_d=\frac{2X_d-X_q}{2}\sqrt{2}I\cos(2\sigma+\phi)+\frac{X_q}{2}\sqrt{2}I\cos\phi$$

$$v_q=\frac{2X_q-X_d}{2}\sqrt{2}I\sin(2\sigma+\phi)-\frac{X_d}{2}\sqrt{2}I\sin\phi$$

$$v_0=0 \tag{34}$$

By equations 11

$$v_\alpha=\frac{2X_d-X_q}{4}\sqrt{2}I\,[\cos(\sigma+\phi)+\cos(3\sigma+\phi)]+\frac{X_q}{2}\sqrt{2}I\cos\sigma\cos\phi+\frac{2X_q-X_d}{4}\sqrt{2}I\,[\cos(\sigma+\phi)-\cos(3\sigma+\phi)]-\frac{X_d}{2}\sqrt{2}I\sin\sigma\sin\phi$$

$$v_\beta=\frac{2X_d-X_q}{4}\sqrt{2}I\,[\sin(3\sigma+\phi)-\sin(\sigma+\phi)]+\frac{X_q}{2}\sqrt{2}I\cos\phi\sin\sigma-\frac{2X_q-X_d}{4}\sqrt{2}I\,[\sin(\sigma+\phi)-\sin(3\sigma+\phi)]+\frac{X_d}{2}\sqrt{2}I\sin\phi\cos\sigma$$

$$v_0=0 \tag{35}$$

The driving voltage behind such a fault is in phase with the voltage of phase a. If it is assumed that the fault current lags the driving voltage by 90 degrees, the current in phase a may be written

Figure 7. Clarke component networks for the analysis of line-to-ground fault beyond delta-Y transformer with solidly grounded neutral

(A) 3-phase circuit. (B) Component networks. jX_T is the reactance of the transformer, per phase, referred to high-voltage side. The transformer turn ratio per leg is 1:n

$$i_a=\sqrt{2}I\sin\left(\sigma-\frac{\pi}{2}\right)$$

$$\phi=-\frac{\pi}{2}$$

Neglecting the third harmonic components and setting $\phi=-\pi/2$

Figure 8. Clarke component network for the analysis of line-to-line fault beyond delta-Y transformer

(A) 3-phase circuit. (B) Component networks

$$v_\alpha=\frac{3X_d+X_q}{4}\sqrt{2}I\sin\sigma$$

$$v_\beta=-\frac{X_d-X_q}{4}\sqrt{2}I\cos\sigma$$

$$v_0=0 \tag{36}$$

The components of the assumed currents are, from equations 2

$$i_\alpha=i_a=\sqrt{2}I\sin\left(\sigma-\frac{\pi}{2}\right)$$

$$i_\beta=0$$

$$i_0=0 \tag{37}$$

Under this condition, the general network equations 6 become

$$V_\alpha=I_\alpha Z_{\alpha\alpha}$$
$$V_\beta=I_\alpha Z_{\beta\alpha}$$
$$V_0=I_\alpha Z_{0\alpha} \tag{38}$$

or

$$Z_{\alpha\alpha}=\frac{V_\alpha}{I_\alpha}$$

$$Z_{\beta\alpha}=\frac{V_\beta}{I_\alpha}$$

$$Z_{0\alpha}=\frac{V_0}{I_\alpha} \tag{39}$$

Converting equations 36 and 37 to phasor form and making a substitution in equations 39, it is found that

$$Z_{\alpha\alpha}=j\frac{3X_d+X_q}{4}$$

$$Z_{\beta\alpha}=\frac{X_d-X_q}{4}$$

$$Z_{0\alpha}=0 \tag{40}$$

Again it is necessary to find current distribution in only one network, the α-network, and then calculate the voltages induced in the β-current. An equivalent circuit for the analysis of this problem is shown in Figure 8. The representation of the delta-Y transformer is discussed in Appendix II.

Line-to-Neutral Fault on the Generator Terminals

A line-to-neutral fault on the generator terminals causes the flow of α- and 0-currents in the generator, as shown in Figure 9.

As indicated in equations 8, α-currents produce flux linkages only in the direct and quadrature axis windings and 0-currents produce flux linkages only in the zero sequence winding. Since there is no interaction between the two components, they may be considered separately.

The α- and β- networks will be the same as in the previous section, and the 0-network will be the usual network.

Thus

Figure 9. Clarke component networks for the analysis of single line-to-neutral fault at the generator

(A) 3-phase circuit. (B) Component networks

$$Z_{\alpha\alpha}=j\frac{3X_d+X_q}{4}$$
$$Z_{\beta\alpha}=\frac{X_d-X_q}{4}$$
$$Z_{\alpha\beta}=Z_{\gamma\alpha}=0$$
$$Z_{00}=Z_0 \qquad (41)$$

The interconnection of the networks for this analysis is shown in Figure 9.

A 2-line-to-neutral fault on generator terminals will not be considered here since such a fault occurs rarely and does not seem to be of primary importance. If such a fault were to occur on the high-voltage side of a delta-Y transformer, of course, only β-currents would flow in the generator windings.

Conclusions

Upon examination of the results of the preceding development, it may be seen that the Clarke component network representative of a synchronous machine for the purposes of short circuit analysis takes on two forms, one being a simplification of the other.

Figure 10(A) shows the Clarke component network to be used in the analysis of a balanced 3-phase short circuit. The characteristic impedances of this network are

$$Z_{\alpha\alpha}=Z_{\beta\beta}=jX_d$$
$$Z_{\alpha\beta}=Z_{\beta\alpha}=Z_{0\alpha}=Z_{\alpha 0}=0 \qquad (42)$$

Figure 10(B) shows the Clarke component network to be used in the analysis of all other types of short circuits considered here. The characteristic impedances of this network are

$$Z_{\alpha\alpha}=Z_{\beta\beta}=j\frac{3X_d+X_q}{4}$$
$$Z_{\alpha\beta}=-Z_{\beta\alpha}=-\frac{X_d-X_q}{4}$$
$$Z_{0\alpha}=Z_{\alpha 0}=Z_{0\beta}=Z_{\beta 0}=0$$
$$Z_{00}=Z_0 \text{ (the usual zero sequence impedance)} \qquad (43)$$

Since X_d is given three times the weight of X_q in equation 43, the difference between the values for $Z_{\alpha\alpha}=Z_{\beta\beta}$ in equations 42 and 43 will be small so that either value of $Z_{\alpha\alpha}=Z_{\beta\beta}$ may be used in practical applications and a-c network calculating board studies for all the various kinds of faults considered in this paper.

To summarize the results it can be stated:

1. Clarke component impedances which are involved in short circuit analysis do not vary with the type of unbalanced fault. For a 3-phase fault, the appearance of the network seems to change but upon examination it is seen that this is but a simplification of the more general network allowable for this one case.

2. Expressions for all component impedances are relatively simple with the exception of the mutual impedances between the α- and β-networks. It appears that this is a nonreciprocal mutual impedance ($Z_{\alpha\beta}=-Z_{\beta\alpha}$). From the standpoint of short circuit analysis by means of a network calculator, this would appear to be a disadvantage. However, it

Figure 11. Clarke component current distribution in delta-Y transformer

(A) α-currents on Y side produce β-currents on delta side, and (B) vice versa

is shown in Appendix III that it is permissible to analyze either the α- or the β-network independently and introduce later the effect of the mutual impedance. For instance, suppose the β-network is short circuited as in Figure 13. Current distribution is found in the β-network neglecting the very small effect of $I_\alpha Z_{\beta\alpha}$. Later the voltage induced in the α-network, $I_\beta Z_{\alpha\beta}$, may be calculated and its effect upon the α-network examined.

3. In each case considered, the number of Clarke component networks which must be solved for current distribution is less than, or equal to, the number of component networks which would have to be so solved if symmetrical components were used.

4. From the results of the analysis of component impedances, it would seem that Clarke components do have some physical significance, more so, at least, than the negative sequence reactance.[19]

Appendix I. Terminology

a, b, c, n = designation of the phase and neutral in a 3-phase system

α, β, 0 = designation of Clarke component quantities and networks

I_a, I_b, I_α = phasor currents in subscript conductor

V_a, V_b, V_α, E_a, E_b = phasor voltages on subscript conductor. (The symbol E implies a generated or driving electromotive force)

i_a, i_α, v_a, v_α, e_a = instantaneous currents and voltages

i_d, i_q, e_d, e_q = instantaneous direct and quadrature axis currents and voltages, respectively, of a synchronous machine

Λ_a, Λ_d, and so forth = flux linkages of subscript winding

σ = electrical position of direct axis with respect to the axis of phase a

ϕ = phase angle between fault current and driving voltage

$Z_{\alpha\alpha}$, $Z_{\beta\beta}$, and so forth = self impedance between subscript networks

$Z_{\alpha\beta}$, $Z_{\beta\alpha}$, and so forth = mutual impedance between subscript networks. The first subscript is the network acted upon, thus, $V_1 = I_k Z_{1k} + \ldots$

L_d, L_q, X_d, X_q = direct and quadrature axis inductances and reactances respectively, of a synchronous machine

X_s = a symmetrical 3-phase reactance between generator terminals and fault position

Appendix II. Clarke Component Analysis of a Delta-Y Transformer

The delta-Y transformer has often entered in the preceding discussion and its analysis in terms of Clarke components is included here to complete the picture.

It can be seen from Figure 11(A) that β-currents flow in the leads to the delta-connected windings when α-currents are circulated in the Y-connected windings. It is shown there that the ratio between the component currents in the leads on either side of the transformer is merely the effective turn ratio of the transformer. That is

$$I_{\alpha Y} = I_A,\ I_{\beta Y} = 0$$
$$I_{\alpha\Delta} = 0,\ I_{\beta\Delta} = \sqrt{3}nI_A = \sqrt{3}nI_{\alpha Y} \tag{44}$$

Similarly, Figure 11(B) indicates that β-currents flowing in the Y-connected windings cause the flow of α-currents in the phase wire on the delta side. It is shown that

$$I_{\alpha Y} = 0,\ I_{\beta Y} = \frac{2}{\sqrt{3}} I_B$$
$$I_{\alpha\Delta} = 2nI_B = \sqrt{3}nI_{\beta Y},\ I_{\beta\Delta} = 0 \tag{45}$$

From these relationships, it is evident that the α- and β-networks are cross-connected and coupled by transformers of a turn ratio $\sqrt{3}n$:1 to represent the delta-Y transformer.

The nature of the component transformer impedances may be examined by considering the delta terminals to be short circuited while currents are circulated in the Y side. Then, if α-currents circulate in the Y-connected windings as shown in Figure 11(A)

$$E_A = I_A Z_T$$
$$E_B = E_C = -\frac{1}{2} I_A Z_T \tag{46}$$

where Z_T is the transformer impedance per leg, referred to Y-side voltage.

By changing these voltages and currents to Clarke components

$$E_{\alpha Y} = I_A Z_T$$
$$I_{\alpha Y} = I_A \tag{47}$$

or

$$Z_{\alpha Y} = \frac{E_{\alpha Y}}{I_{\alpha Y}} = Z_T \tag{48}$$

The α-loop impedance of the transformer is positive sequence impedance.

Similarly, from Figure 11(B)

$$E_{\beta Y} = \frac{2}{\sqrt{3}} I_B Z_T$$
$$I_{\beta Y} = \frac{2}{\sqrt{3}} I_B \tag{49}$$

or

$$Z_{\beta Y} = \frac{E_{\beta Y}}{I_{\beta Y}} = Z_T \tag{50}$$

The β-loop impedance also is positive sequence impedance.

The network which satisfied equations 44 and 45 and includes the transformer impedances is shown in Figure 12. The zero network is familiar from symmetrical component analysis.

In this treatment, the terminals of the transformer are not marked in the conventional manner to give a phase shift of 30 degrees between correspondingly marked phases. Rather, they have been marked for convenience in short circuit analysis. For this purpose, the notation of the terminals is of no significance as long as consistency is maintained.

If a per-cent or per-unit method of calculation is used, the coupling transformers in Figure 12 are eliminated and the cross connection made directly.

Figure 12. Clarke component network of delta-Y transformer

(A) 3-phase circuit. (B) Component network. Z_T is the transformer reactance per leg referred to the Y side voltage

Appendix III. Analyses Involving Two or More Machines

In the analyses of the various cases of short circuits, the effect of a second generator on the systems was not considered. It was assumed that currents flowed in either the α- or β-networks but not in both simultaneously. The presence of a second source closes both the α- and β-loops so that currents may be induced in the network previously considered to have none.

An exact analysis of this problem would be somewhat difficult since a nonreciprocal mutual impedance, $Z_{\alpha\beta} = -Z_{\beta\alpha}$, becomes involved. Therefore, the examinations of a particular example in order to obtain a conception of relative values and determine what simplifying assumptions may be made will be valuable.

Consider the case shown in Figure 13 of two generators connected by a transmission line which is faulted line-to-line at some point.

Writing circuit equations for the component networks in Figure 13 gives

$$0 = I_\alpha(Z_{\alpha\alpha 1} + Z_{\alpha\alpha 2} + Z_1 + Z_2) + I_{\beta 1} Z_{\alpha\beta 1} - I_{\beta 2} Z_{\alpha\beta 2}$$
$$E_\beta = I_{\beta 1}(Z_{\beta\beta 1} + Z_1) + I_\alpha Z_{\beta\alpha 1}$$
$$E_\beta = I_{\beta 2}(Z_{\beta\beta 2} + Z_2) - I_\alpha Z_{\beta\alpha 2} \tag{51}$$

The first of equations 51 may be rearranged to find

$$I_\alpha = \frac{-I_{\beta 1} Z_{\alpha\beta 1} + I_{\beta 2} Z_{\alpha\beta 2}}{Z_{\alpha\alpha 1} + Z_{\alpha\alpha 2} + Z_1 + Z_2} \tag{52}$$

To make this case most extreme, set Z_1, Z_2, and $Z_{\alpha\beta 1}$ equal to zero. This means that the generators are connected together on one bus and number one is a cylindrical rotor machine. Then equation 52 becomes

$$\frac{I_\alpha}{I_{\beta 1}} = \frac{Z_{\alpha\beta 2}}{Z_{\alpha\alpha 1} + Z_{\alpha\alpha 2}} \tag{53}$$

Values of typical machine reactance may be assumed and the ratio of I_α to $I_{\beta 1}$ evaluated. For example, if

$$X_{d1} = 40 \text{ per cent}$$
$$X_{q1} = 40 \text{ per cent}$$
$$X_{q2} = 70 \text{ per cent} \tag{54}$$

Then

$$\frac{I_\alpha}{I_{\beta 1}} = -j0.086 \tag{55}$$

Introducing this ratio into the third of equations (51)

$$E_\beta = \underbrace{I_{\beta 1} j47.5}_{I_{\beta 1} Z_{\beta\beta}} - \underbrace{I_{\beta 1} j0.65}_{I_\alpha Z_{\alpha\beta}} \tag{56}$$

Thus, it is seen that even in extreme cases the influence of the α-circulating currents on the β-network is very small and may be disregarded. It is only necessary in such cases to find the current distribution in the β-network and then calculate induced voltages and circulating currents in the α-network. A similar examination of the case of α-fault currents would show the same result.

Discussion

Edward W. Kimbark (Northwestern University, Evanston, Ill.): Clarke components were introduced in 1938, but their usefulness in the solution of unbalanced 3-phase circuits is not yet fully appreciated. The present paper by Camburn and Gross and another paper by Duesterhoeft[1] are welcome because they indicate an increase of interest in Clarke components. There are still promising opportunities, however, for further work in exploring the application of these components to both steady-state and transient problems, either as substitutes for, or as adjuncts to, Fortescue's symmetrical components and Park's direct- and quadrature-axis components.

Camburn and Gross show that the α and β networks of a synchronous machine are as given in their Figures 6 and 10(B): with electromotive forces, E_α and E_β equal to one another in magnitude and 90 degrees apart in phase, with equal self-impedances

$$Z_{\alpha\alpha} = Z_{\beta\beta} = j(3X_d + X_q)/4 \qquad (1)$$

and with nonreciprocal mutual impedances

$$Z_{\alpha\beta} = -Z_{\beta\alpha} = -(X_d - X_q)/4 \qquad (2)$$

The same results could have been obtained more briefly by starting with equations 2B of my 1939 paper,[2] which (after changing the notation to agree with Miss Clarke's) give the Clarke impedances of a 3-phase rotating machine in terms of the Fortescue impedances as

$$Z_{\alpha\alpha} = Z_{\beta\beta} = (Z_{11} + Z_{22})/2 \qquad (3)$$

$$Z_{\alpha\beta} = -Z_{\beta\alpha} = j(Z_{11} - Z_{22})/2 \qquad (4)$$

Here Z_{11} and Z_{22} are the positive- and negative-sequence self-impedances, respectively. Let us substitute into equations 3 and 4 for the positive-sequence impedance

$$Z_{11} = jX_d \qquad (5)$$

and for the negative-sequence impedance its common value

$$Z_{22} = j(X_d + X_q)/2 \qquad (6)$$

In equations 5 and 6, X_d and X_q have been written instead of x_d'' and x_q'' for the sake of agreement with the notation in the paper under discussion. More will be said about this later. The value of Z_{22} given by equation 6 is correct for sinusoidal negative-sequence current.[1] Upon substituting, we obtain expressions for the Clarke impedances identical with those found by Camburn and Gross (equations 1 and 2 of this discussion).

It seems preferable, however, because of the variation of both Z_{11} and Z_{22}, to leave the expressions for the Clarke impedances of a rotating machine in the form of equations 3 and 4 instead of obtaining equations 1 and 2 by substitution of equations 5 and 6. Consider first the variation of negative-sequence impedance Z_{22}. It is well known that the negative-sequence reactance of a synchronous machine varies with the external circuit conditions, such as the type of short circuit, the highest value of this reactance occurring for sinusoidal negative-sequence current, the lowest value for sinusoidal negative-sequence voltage, and various intermediate values for line-to-ground, line-to-line, and 2-line-to-ground short circuits. Camburn and Gross claim that, by contrast, the Clarke impedances of a synchronous machine are independent of the type of short circuit. I believe, however, that this claim is based on fallacious reasoning. The authors have assumed in their derivations that, during every type of short circuit, the Clarke currents are sinusoidal. In consequence, they have obtained Clarke impedances (equations 1 and 2) which implicitly contain the corresponding value of negative-sequence reactance, equation 6. They should have found the actual wave form of the Clarke currents for each type of fault and then should have taken the fundamental-frequency components of such currents for use in determining the impedances. For example, Duesterhoeft gives the β current during a line-to-line short circuit in his equation 24 and the fundamental component in his equation 25. From this fundamental current and the sinusoidal β electromotive force, we obtain the β self-impedance as

$$Z_{\beta\beta} = j(x_d'' + \sqrt{x_d'' x_q''})/2 \qquad (7)$$

This value is the one that is obtained by substituting into equation 3 of this discussion

$$Z_{11} = jx_d'' \text{ and } Z_{22} = j\sqrt{x_d'' x_q''} \qquad (8)$$

the latter being the value of negative-sequence impedance of a machine during a line-to-line short circuit according to previous papers.

Second, consider the variation of the positive-sequence impedance Z_{11} both with power factor and with time-rate of change of positive-sequence current. As power factor varies, Z_{11} varies between jX_d and jX_q. If we restrict the power factor to zero, as it is very closely during short circuits with negligible external resistance, Z_{11} equals jX_d, as given by equation 5. However, X_d can still vary with the rate of change of positive-sequence current from the subtransient value, written x_d'', through the transient value x_d', to the synchronous value x_d. Regardless of which value of X_d is used for positive-sequence impedance, the X_d and X_q associated with the negative-sequence impedance should always be the subtransient values x_d'' and x_q''. So equations 1 and 2 really combine into one symbol two values of X_d which may very well differ, one being associated with the positive-sequence impedance and the other with the negative-sequence impedance.

The difficulty of nonreciprocal coupling between the α and β networks, which is discussed in Appendix III, disappears if we make the β network contain current jI_β instead of I_β and voltage jV_β instead of V_β, in other words, if we use the sum and difference of positive- and negative-sequence quantities instead of α and β quantities in the substitute networks. The nonreciprocal mutual impedance now becomes a reciprocal one, equal to $(Z_{11} - Z_{22})/2$, and the equivalent circuit corresponding to Figure 13 of the paper becomes that shown in Figure 1 of this discussion. The new circuit has the additional advantage of using only one set

Figure 1. Substitute networks corresponding to Figure 13 of the paper but with reciprocal mutual impedances

of electromotive forces in the two substitute networks. Another example of the use of the sum and difference of positive- and negative-sequence quantities to a problem in rotating machinery connected to an unbalanced circuit is contained in Problem 3 and Figure 1 of my 1939 paper.[2]

R. D. Camburn and Eric T. B. Gross: We are indeed grateful to E. W. Kimbark for his discussion, since he emphasizes a few points which may be by-passed by the reader. This is especially true with regard to the values (x_d, x_d' and x_d'', x_q and x_q'') that should be assigned to X_d and X_q, as is mentioned in the paper in the section on Component Network Impedances under Fundamental Relationships.

In our opinion, it is more than a matter of taste whether reference is made to Blondel-Park 2-reaction reactances, or to some kind of derived quantities, as for example, sequence reactances. It appears that Blondel-Park reactances are basic quantities which have real physical meaning. This viewpoint leads to the desire to derive expressions for Clarke reactances directly, and without the detour through symmetrical components.

It now is generally understood (see ASA Standard C 42, 10.35.170)[1] that "the negative sequence reactance is the ratio of the fundamental component of reactive armature voltage, due to the fundamental negative-sequence component of armature current, to this component of armature current at rated frequency." Therefore, it is logical and in line with present day practice[2,3] to follow the procedure outlined in our paper, that is, to assume circulating sinusoidal currents for the derivation of Clarke reactances expressed by Blondel-Park reactances.

The variation of negative sequence reactance values has been discussed in detail by W. A. Lewis,[4,5] and he found five different values for the "negative sequence" reactance for short circuits at the terminals. However, system short circuits, as considered in the paper, involve substantial external impedances which minimize the harmonic effects. Furthermore, since x_d'' and x_q'' are very nearly equal for modern machines with adequate damper circuits, the harmonics will normally be very small in any case. Thus the assumption of sinusoidal currents is usually justified. It is well known, as stated by Kimbark, that the assumption of harmonic currents or sinusoidal voltages will lead to other reactance values,[4] but these are by no means the "true" ones, or of greater significance than the values in his equations 1 and 2. Of course, Kimbark's remarks are a most welcome supplement to our paper.

The modification suggested in the last paragraph of Kimbark's discussion may serve as a beautiful example of simplification through a slight variation of Clarke components.

Power Factor Measurements on Polyphase and Multiconductor Cable Using Single-Phase Bridges

E. W. GREENFIELD
MEMBER AIEE

THE accurate measurement of dielectric losses in modern, low-loss power cable is generally accomplished by means of various types of bridge circuits. Perhaps the most accurate and useful circuit for high-voltage cable testing is the Schering bridge in one form or another. Such bridges are capable of operation at very high voltages depending only upon the voltage limitation of the reference standard capacitor. When provided with suitable shunts, they also can measure a wide range of cable sizes and lengths.

Figure 1 shows a highly developed form of Schering bridge utilized in the author's company for the measurement of power factor and capacitance of high-voltage cable. Using a compressed gas reference capacitor, the bridge is capable of operating up to 150 kv and can handle charging currents from 0.014 to 10 amperes through a system of 13 shunts in the low-voltage arm. Accuracy in power factor (actually the bridge reads directly in dissipation factor) is the larger of 1 per cent of the reading or 10 microradians over the range 0-10 per cent dissipation factor; capacitance accuracy is ±0.5 per cent. The bridge is provided with a balancing guard circuit system substantially at ground potential which eliminates strong pick-up and end influences and permits accurate definition of the electrode system under test.

Limitation of Bridge Circuits in Polyphase Systems

All such bridges are essentially single-phase devices and normally cannot be used with multiphase voltage sources—for example, in a 3-phase system, to determine the 3-phase power factor of a 3-conductor cable. It is quite possible however through proper use of the bridge's guard circuit, to measure the polyphase power factor of any polyphase system using single-phase voltages. It also is possible to determine the mutual phase angles and capacitances between any system of conductors in a multiconductor cable from single-phase measurements properly taken.

It is the purpose of this paper to illustrate how this may be accomplished and to that end, two very important examples will be described. The first of these is the 3-conductor metallic-sheathed belted cable for which it will be shown how a guarded bridge circuit using single-phase voltage may be employed to obtain 3-phase power factor. The second example is the 2-conductor metallic-sheathed nonbelted cable which is used widely in many specialized circuits. Here the objective will be the determination of power factor and capacitance under operating conditions of voltage distribution.

The 3-Conductor Belted Cable

Measurement of 3-Phase Power Factor by Single-Phase Bridge

There is obviously no problem or question with regard to the power factor measurement for 3-conductor shielded cables. There also is no question involved for 3-conductor nonshielded cables providing the measurement is made with 3-phase equipment. A Y-connected 3-wattmeter method will always give total true power absorbed by a Y load and if the load is balanced, a phase power factor can always be determined which applies to the system as a whole. Unfortunately wattmeters cannot be used for measuring power factors of cables since they are far too insensitive. A 3-conductor belted cable has unshielded conductors and application of a single-phase bridge measuring device must take into account the mutual field configuration when connected to its normal voltage source.

When single-phase voltage and measurement are to be used, two important questions arise at once:

1. What values of voltage shall be applied between sheath and conductors as compared with that between conductors?
2. How shall equivalent 3-phase power factor be computed?

Definition of 3-Phase Power Factor

No answer to these questions can be attempted until the term "equivalent 3-phase power factor" is acceptably defined. Three-phase power factor may be defined as follows: "three-phase power factor is that parameter which when multiplied by the line (or phase) current and the phase voltage (in a Y-connected system) will give the true watt power consumed per phase."

This definition is completely adequate so long as the system is balanced as to voltages and loads. For unbalanced systems there is no single parameter that may be defined as 3-phase power factor.

Based on the foregoing, it is thus required that "equivalent 3-phase power factor" be understood to mean that value computed from single-phase measurements which yields 3-phase power factor as defined above. With this interpretation the answers to the questions raised

Paper 50-107, recommended by the AIEE Insulated Conductors and approved by the AIEE Technical Program Committee for presentation at the AIEE North Eastern District Meeting, Providence, R. I., April 26-28, 1950. Manuscript submitted June 22, 1949; made available for printing March 2, 1950.

E. W. Greenfield is Supervisor of the Electrical Laboratory, Anaconda Wire and Cable Company, Hastings-on-Hudson, N. Y.

Figure 1. Commercial form of high-voltage high-current Schering bridge

above are found by simple but rigorous analysis of the belted cable circuit.

Voltage Stresses

When a nonshielded cable (belted) is connected to a 3-phase source (assumed Y-connected) the voltages across its structure are as follows:

1. Between conductors:—line voltage.
2. Conductor to sheath:—phase voltage (line voltage $\div \sqrt{3}$).

Hence the dielectric between conductors is stressed by a factor equal to $\sqrt{3}$ times the potential across the dielectric between any individual conductor and sheath.

Formula for Equivalent 3-Phase Power Factor

Consider a nonshielded (belted) cable connected to a 3-phase balanced wye source. The cable is the load; the energy consumed in the cable is supplied by the source. Energy is consumed in the cable as a result of its dielectric losses which arise from the fact that various portions of its dielectric structure are subjected to electrical stresses.

Figure 2 shows such a nonshielded cable connected to its 3-phase source. For balanced conditions, the total watts

Figure 2. 3-phase belted cable

Figure 3. Equivalent circuit of a belted cable

absorbed by the cable load is equal to three times the power consumed per phase. The cable load may be represented schematically as shown in Figure 3. Here the dielectric between conductors and to sheath are represented by appropriate admittances (Y). There are three similar admittances between conductors and three similar admittances to sheath. The cable load is thus seen to be composed of a wye circuit in parallel with a delta circuit, Figure 3. Such a circuit can be treated readily by transposing the delta circuit to an equivalent wye and then adding the resulting paralleled wye circuits together to form a single equivalent wye. The steps are given in detail in Appendix II. The final computation is based on a perfectly symmetrical cable structure.

The single admittance in each phase of the equivalent wye load, Figure 3(D) is made up of conductance (G) and capacitance (C) values for both conductor-to-sheath dielectric and conductor-to-conductor dielectric paths. From these values one readily computes the phase power factor which as defined above is the true 3-phase power factor of the cable. Appendix II shows the computation in detail with the results as follows

$$\text{3-phase power factor} = \frac{3C_{12}DF_{12}+C_1DF_1}{3C_{12}+C_1} \quad (1)$$

where:

C_{12} = capacitance between conductor 1 and 2
DF_{12} = dissipation factor between conductor 1 and 2
C_1 = capacitance between conductor 1 and sheath
DF_1 = dissipation factor between conductor 1 and sheath

For values over 10 per cent, the power factor should be corrected from tan ϕ to cos θ as indicated in Appendix II.

Computation of 3-Phase Power Factor From Single-Phase Measurements

Equation 1 can be used to determine 3-phase power factor when C_{12}, DF_{12}, C_1, and DF_1 are known. These values are measured readily by single-phase voltages and a guarded Schering bridge. Guard circuits are necessary so as to eliminate all but the desired dielectric path from the measurement. It is recalled here that bridges read directly in dissipation factor not in power factor.

The capacitance and dissipation factor between conductors are determined at the stresses corresponding to those specified; namely, 20 and 100 volts per mil.* The single-phase voltages used must be computed on the basis of the total insulation thickness between conductors. The capacitance and dissipation factor from conductor to sheath are determined at single-phase voltages which correspond to phase stresses; namely, the conductor-to-conductor voltages divided by $\sqrt{3}$.

Equation 1 is based on a perfectly symmetrical cable. For actual cable, it may be desired to use the average "between-conductor" value and the average "conductor-to-sheath" value. These values may be obtained by three "between-conductor" measurements and one "conductor-to-sheath" measurements. The "between-conductor" measurements are made from one conductor to a second conductor, placing the third conductor and sheath in the guard circuit. The "conductor-to-sheath" measurement is made from the three paralleled conductors to the sheath. Equation 1 then becomes

$$\text{3-phase power factor} = \frac{(C_{12}+C_{23}+C_{31})(DF_{12}+DF_{23}+DF_{31})+C_s\times DF_s}{3(C_{12}+C_{23}+C_{31})+C_s} \quad (2)$$

*Industry specifications for impregnated paper power cables require that the power factor be determined at two insulation stress levels. These are generally at 100 volts per mil and at 20 volts per mil average stress.

Figure 4. Analysis of electrical circuits of a 3-phase belted cable

where

C_s and DF_s = the measured capacity and dissipation factor between all three conductors in parallel to sheath.

When $(C_{12}+C_{23}+C_{31})=C_s$, equation 2 reduces to

$$\text{3-phase power factor} = (DF_{12}+DF_{23}+DF_{31}+DF_s)/4 \quad (3)$$

Equation 3 indicates simply that the dielectric between conductors and sheath contributes only 25 per cent to the over-all 3-phase power factor.

Suggested Factory Procedure for Single-Phase Tests

It is felt that symmetry of construction and uniformity of materials in present-day cable manufacture preclude the necessity of making four separate measurements as prescribed by the averaging method given by equation 2. Two measurements only are felt to be necessary, namely:

1. Conductor-to-conductor: 1 versus 2 and 3, with sheath to guard.
2. 3 conductors-to-sheath: 1, 2, 3, versus sheath.

These measurements will automatically average 67 per cent of the dielectric paths between conductors, and 100 per cent of those between conductors and sheath.

Appendix I gives in detail the suggested factory procedure for determining 3-phase power factor from single-phase bridge measurements based on the above, also a formula for 60-cycle loss.

The 2-Conductor Sheathed Cable

Measurement of Working Parameters by Single-Phase Bridge

It is often required to measure the power factor and capacitance of a metallic sheathed 2-conductor cable. Such cable when classified for power usage finds wide application in series lighting service and other fields where single-phase power is required with full conductivity "go" and "return." For communication and control the shielded twin must be used for all balanced line services. For power application there may or may not be a belt over the conductor insulations; for communication or control no belt is used.

In almost all uses of this type of cable, the two conductors operate as nearly balanced to ground as possible. Power sources are of the center-tap-grounded variety, so that the voltage between conductors is twice the voltage of either conductor to sheath, which, of course, is solidly grounded.

The determination of power factor and capacitance of such a cable has significance only if evaluated under the same conditions of operation, namely the balanced-to-ground condition. This means it is required to evaluate the input impedance of such a cable looking directly into the two conductors with sheath grounded and voltages properly distributed. The usual Schering bridge is essentially a one-grounded-point network and cannot measure the cable impedance under the balanced condition required. However, by making several measurements it is possible to determine the separate impedances between conductors and between conductors and sheath. These may then be combined to give the power factor and capacitance sought.

Analysis of 2-Conductor Metallic-Sheathed Cable

Figure 5 shows a section of a 2-conductor metallic-sheathed cable. The dielectric paths between components are shown as capacitances shunted by conductances. There are three such admittances and their values combine to give the cable its operating characteristics.

Figure 6 (A) is the equivalent electrical circuit. The admittance seen between terminals 1 and 2 determines the operating power factor of the cable. This admittance is made up of the direct admittance between the two conductors paralleled by the admittance of each conductor to sheath in series. This network is readily reduced to an equivalent conductance in shunt with an equivalent capacitance.

Using the notation given in Figure 6 and assuming $C_a = C_b$ and $DF_a = DF_b$, the equations for operating capacitance and power factor of the cable are

$$C = \frac{C_a+2C_{12}}{2} \quad (4)$$

$$PF = \frac{C_aDF_a+2C_{12}DF_{12}}{C_a+2C_{12}} \quad (5)$$

Appendix IV gives the complete derivation of these equations.

To evaluate the operating capacitance and power factor of the cable, it is necessary to determine C_a, C_{12}, DF_a, and DF_{12} at the electric stresses existing during operation. This means that the measurement between conductor and sheath must be limited to the voltage corresponding to that which would normally exist across this region when the operating voltage is applied between conductors. For the 2-conductor sheathed cable operating balanced-to-ground, the voltage between each conductor and sheath will be one half that between conductors.

Measurement of Power Factor and Capacitance

Using a standard, guarded, high-voltage Schering bridge it is possible to measure the constants required by equations 4 and 5. To measure DF_a and C_a, the two conductors are joined and one half the operating voltage applied between these and the sheath. This will give an average of the dissipa-

Figure 5. Section of a 2-conductor metallic-sheathed cable

tion factors between conductors and sheath and the sum of each conductor's capacitance to sheath. Dividing the latter by two gives the average capacitance to sheath. This method of measuring to-sheath dissipation factors and capacitances is justified since the cable geometry is symmetrical to better than a few per cent.

C_{12} and DF_{12}, the direct capacitance and dissipation factor between conductors, can be measured by making the cable sheath part of the bridge guard circuit. This measurement is made with full operating voltage between conductors. Since the sheath will, during guard balancing, be brought to the same potential as the low conductor for the duration of the measurement there will be twice normal voltage across the conductor-to-sheath insulation.

In certain bridge systems it will be found impossible to make the between-conductor measurements using the guard circuit as described before. In this case it will be necessary to measure between one high conductor and the second conductor connected to sheath. A second measurement may be made with the conductors reversed and the two sets of results averaged. The capacitance and dissipation factors so obtained, C_e and DF_e are made up of the impedance between conductors, in parallel with the impedance from the high conductor to sheath. Knowing the impedance between conductor and sheath from the first measurement (C_a and DF_a) it then is possible to compute C_{12} and DF_{12} as follows

$$C_{12} = C_e - C_a \tag{6}$$

$$DF_{12} = \frac{C_e DF_e - C_a DF_a}{C_e - C_a} \tag{7}$$

These are then substituted in equations 4 and 5 as previously. A note of caution must be entered here regarding equation 7. Since the values of C_e and DF_e are determined with the same voltage between conductors as between conductors and sheath, it is required that the C_a and DF_a to be used in equation 7 be those for that voltage. Capacitance has negligible change with voltage; the dissipation factor, DF_a, however, may change with voltage and be larger than when measured at one half operating voltage as required for equation 5. It will, therefore, be necessary to make the measurements for C_a and DF_a, at two voltages, full operating and one half operating, the former for use in equation 7, the latter for equation 5.

Appendix III gives a recommended

Figure 6. Equivalent electrical circuits of a 2-conductor metallic-sheathed cable

factory test procedure based on the above analysis. Data for an actual, full reel length cable are included as an example of the method and the computations.

If it is desired to measure the true power factor of the cable at a high stress, for example 100 volts per mil, with the Schering bridge, it must be remembered that during the period of measurement the insulation between conductors and sheath will be subjected to 200 volts per mil when no belt insulation is present. This is generally not good practice and should be avoided.

Field Configuration

It may be asked purposefully how the field configurations in the cable differ when single-phase voltages are used for example, in place of 3-phase sources and how such differences might affect power factor values.

An anisotropic media such as a belted impregnated paper-insulated cable which also is subject to local ionizing regions might be expected to show losses which are more dependent on the electric field configuration than on over-all potential differences.

A qualitative analysis of single-phase fields versus 3-phase fields indicates that the space distributions between conductors and conductors and sheath are not essentially different. The time-phase differences in a 3-phase source system bring the individual conductors to maximum potential differences at 1/6th of a cycle intervals. However, in any one cycle all conductors each have one positive and one negative maximum potential difference. During each instant of maximum potential difference, one conductor is at its maximum potential and the other two are at a lower (opposite in sign) but equal potential. Hence at this instant the field configuration is the same as for single-phase voltages applied between one high conductor and the other two joined as low.

Since the space shape of the fields is similar and the net ionizing time per cycle is the same, it is expected that power factor values obtained by means of the single-phase methods described before are valid for 3-phase operation.

Appendix I. Suggested Factory Procedure for 3-Phase Power Factor Measurements on Belted Cable*

1. Measure conductor 1 versus 2 and 3 with sheath on guard circuit. Use 20 and 100 volts per mil (vpm) calculated from two times the insulation thickness on conductor. Call these voltages $E_{20\ \mathrm{vpm}}$ and $E_{100\ \mathrm{vpm}}$.

(a). Record capacitance, C_g.
(b). Record dissipation factor, DF_g.

2. Measure three conductors to sheath. Use E_{20} vpm/$\sqrt{3}$ and E_{100} vpm/$\sqrt{3}$ for the two voltages.

(a). Record capacitance, C_s.
(b). Record dissipation factor, DF_s.

3. Calculate true 3-phase power factor from

$$PF = \frac{9C_e DF_e + 2C_s DF_s}{9C_e + 2C_s} \tag{8}$$

4. Calculate total 3-phase loss at 60 cycles per second from

$$\text{Watts} = 0.628 \times KV^2 \times PF(9C_e + 2C_s) \tag{9}$$

Where KV = line-to-line voltage in kilovolts, C_e and C_s are expressed in microfarads, and PF = 3-phase power factor from equation 8, expressed in per cent.

Bridge measurements actually give dissipation factors rather than power factors; that is, tan ϕ rather than cos θ. Below 10 per cent, the two have negligible differences. Above 10 per cent, the tan ϕ readings should be corrected to power factor (cos θ). In equation 8 bridge readings, regardless of value, are substituted into the equation. If the resulting solution is greater than 10 per cent it should be corrected from tan ϕ to cos θ.

Appendix II. Derivation of Equivalent 3-Phase Power Factor of a 3-Phase Belted Cable

The cable dielectric is represented by equivalent admittances; that is, conductances in parallel with capacitances. The admittances of the equivalent circuit for a 3-phase belted cable shown in Figure 4(A) are as follows:

CONDUCTOR-TO-CONDUCTOR:

Conductor 1 to 2: $G_{12} + jwC_{12} = Y_{12}$
Conductor 2 to 3: $G_{23} + jwC_{23} = Y_{23}$
Conductor 1 to 3: $G_{13} + jwC_{13} = Y_{13}$

*Based on balanced voltages and load; no harmonics in neutral; Y-connected source.

CONDUCTOR-TO-SHEATH:

Conductor 1 to sheath: $G_1+jwC_1=Y_1$
Conductor 2 to sheath: $G_2+jwC_2=Y_2$
Conductor 3 to sheath: $G_3+jwC_3=Y_3$

Figure 4(B) indicates how the conductor-to-conductor dielectric forms a delta circuit which is in parallel with the wye made up of conductor-to-sheath dielectrics. In Figure 4(C), the delta circuit is transformed to its equivalent wye. The transformation gives

$$Y_{12}'=Y_{12}Y_{13}\left(\frac{1}{Y_{11}}+\frac{1}{Y_{21}}+\frac{1}{Y_{12}}\right)$$

$$Y_{23}'=Y_{23}Y_{13}\left(\frac{1}{Y_{11}}+\frac{1}{Y_{22}}+\frac{1}{Y_{13}}\right)$$

$$Y_{13}'=Y_{13}Y_{23}\left(\frac{1}{Y_{12}}+\frac{1}{Y_{23}}+\frac{1}{Y_{13}}\right)$$

For a symmetrical load (as is the case)

$$Y_{12}=Y_{23}=Y_{13}$$

also

$$Y_1=Y_2=Y_3$$

and the above equations simplify as follows

$$Y_{12}'(=Y_{23}'=Y_{13}')=3Y_{12}(=3Y_{23}=3Y_{13})$$

Figure 4(C) thus shows the equivalent belted cable circuit made up of two wye circuits in parallel which are readily combined to give the single wye circuit shown in Figure 4(D). Here the phase admittances are assumed all equal and are given by

$$\begin{aligned}Y_A(=Y_B=Y_C)&=3Y_{12}+Y_1\\&=3(G_{12}+jwC_{12})+(G_1+jwC_1)\\&=(3G_{12}+G_1)+jw(3C_{12}+C_1)\end{aligned} \quad (10)$$

but

Dissipation factor:—$\tan\phi=\dfrac{G}{wC}$

Substituting dissipation factors for conductances in equation 10, we get

$$Y_A=w[(3C_{12}\tan\phi_{12}+C_1\tan\phi_1)+j(3C_{12}+C_1)] \quad (11)$$

from which

$\tan\phi_A$ (3-phase dissipation factor)

$$=\frac{3C_{12}\tan\phi_{12}+C_1\tan\phi_1}{3C_{12}+C_1} \quad (12)$$

For dissipation factors less than 10 per cent

3-phase power factor:—PF_A

$$=\frac{3C_{12}DF_{12}+C_1DF_1}{3C_{12}+C_1} \quad (13)$$

Appendix III. Recommended Factory Test Procedure for Measuring Capacitance and Power Factor of 2-Conductor Metallic Shielded Cable Using a Schering Bridge

1. Refer to Table I for circuit connections and voltages.

2. Use connection designation AA:
   Record capacitance and dissipation factor.
   Divide capacitance by two to obtain: C_a in microfarads.
   Designate dissipation factor obtained: DF_a (in per cent).

3. Use connection designation C_{12}:
   Record capacitance as: C_{12} in microfarads.
   Record dissipation factor as: DF_{12}, per cent.

4. Calculate cable capacitance and power factor from

$$C=\frac{C_a+2C_{12}}{2}\text{ mfd} \quad (14)$$

$$PF=\frac{(C_aDF_a+2C_{12}DF_{12})}{C_a+2C_{12})}\text{ per cent} \quad (15)$$

5. Where the type of bridge guard employed does not permit balancing of the C_{12} circuit, use:

6. Connection designation AA':
   Record capacitance and dissipation factor.
   Divide capacitance by two to obtain: C_a', microfarads.
   Designate dissipation factor as: FD_a', per cent.

7. Use designations CA and CB:
   Record capacitances and dissipation factors.
   Designate these as: C_{ca}, C_{cb}, DF_{ca}, and DF_{cb}.
   Average C_{ca} and C_{cb} to obtain: C_c, microfarads.
   Average DF_{ca} and DF_{cb} to obtain: DF_c, per cent.

8. Calculate C_{12} and DF_{12} from

$$C_{12}=C_c-C_a'\text{ mfd} \quad (16)$$

$$DF_{12}=\frac{C_cDF_c-C_a'DF_a'}{C_c-C_a'}\text{ per cent} \quad (17)$$

9. Having C_{12} and DF_{12}, substitute these in equations 14 and 15 to obtain the desired capacitance and power factor.

EXAMPLE:

Factory order, 2-conductor, flat, number 6, American wire gauge, solid, 14/64-inch paper, 7/64-inch lead. Length 2,013 feet. Tested September 20, 1945 by the Cable Test Department of the Anaconda Wire and Cable Company.

Using circuit AA:

$C_a=1/2\times0.2032=0.1016$ microfarad
$DF_a=0.413$ per cent

Using circuit C_{12}:

$C_{12}=0.0068$ microfarad
$DF_{12}=0.66$ per cent

Using equation 14

$$C=\frac{C_a+2C_{12}}{2}=\frac{0.1016+2\times0.0068}{2}=$$

0.0576 microfarad

Using equation 11

$$\text{Power factor}=PF=\frac{C_aDF_a+2C_{12}DF_{12}}{C_a=2C_{12}}=$$

$$\frac{0.1016\times0.413+2\times0.0068\times0.66}{0.1016+2\times0.0068}=$$

0.445 per cent

Should the bridge not balance with the C_{12}
